## Abstract

Vascular leak is a hallmark of severe dengue, and high leukotriene levels have been observed in dengue mouse models, suggesting a role in disease pathogenesis. We sought to explore their role in acute dengue, by assessing levels of urinary leukotriene (LTE4) and histamine in patients with varying severity of acute dengue. Urinary LTE4, histamine and creatinine were measured by a quantitative ELISA, in mid-morning urine samples collected from healthy individuals (n= 19) and patients with dengue fever (DF= 72) and dengue haemorrhagic fever (DHF= 48). The kinetics of LTE4 and histamine and diurnal variations were assessed in a subset of patients. Urinary LTE4 levels were significantly higher (p=0.004) in patients who proceed to develop DHF when compared to patients with DF during early illness ([?] 4 days) and during the critical phase (p=0.02). However, LTE4 was not a good predictive marker of DHF as ROCs gave an AUC value of 0.67 (95% CI 0.57 to 0.76), which was nevertheless significant (p=0.002). Urinary LTE4 levels did not associate with the degree of viraemia, infecting virus serotype and was not different in those with primary vs secondary dengue. LTE4, histamine and the viral loads showed a marked diurnal variation in both patients with DF and DHF. Our data suggest that LTE4 could play a role in disease pathogenesis and since there are safe and effective cysteinyl leukotriene receptor blockers, it would be important to assess their efficacy in reducing dengue disease severity.

## Short title: Urinary Leukotrienes in acute dengue

**Keywords:** acute dengue, vascular leak, dengue haemorrhagic fever, leukotrienes, histamine, LTE4, viral loads, diurnal variation

## Abbreviations

DHF: Dengue haemorrhagic fever

DF: Dengue Fever

DENV: Dengue virus

PAF: platelet activating factor

FBC: Full Blood Count

## Summary

Vascular leak is a hallmark of severe dengue, and high leukotriene levels have been observed in dengue mouse models, suggesting a role in disease pathogenesis. We sought to explore their role in acute dengue, by assessing levels of urinary leukotriene (LTE4) and histamine in patients with varying severity of acute dengue.

Urinary LTE4, histamine and creatinine were measured by a quantitative ELISA, in mid-morning urine samples collected from healthy individuals (n= 19) and patients with dengue fever (DF= 72) and dengue haemorrhagic fever (DHF= 48). The kinetics of LTE4 and histamine and diurnal variations were assessed in a subset of patients. Urinary LTE4 levels were significantly higher (p=0.004) in patients who proceed to develop DHF when compared to patients with DF during early illness ([?] 4 days) and during the critical phase (p=0.02). However, LTE4 was not a good predictive marker of DHF as ROCs gave an AUC value of 0.67 (95% CI 0.57 to 0.76), which was nevertheless significant (p=0.002). Urinary LTE4 levels did not associate with the degree of viraemia, infecting virus serotype and was not different in those with primary vs secondary dengue. LTE4, histamine and the viral loads showed a marked diurnal variation in both patients with DF and DHF.

Our data suggest that LTE4 could play a role in disease pathogenesis and since there are safe and effective cysteinyl leukotriene receptor blockers, it would be important to assess their efficacy in reducing dengue disease severity.

## Introduction

Dengue infections are one of the most rapidly emerging mosquito-borne viral infections in the world. It was estimated that 18% of the 58.4 million symptomatic cases of dengue were admitted to hospital in 2013, which is a staggering 10.5 million patients(1). Approximately 26% to 33.6% of hospitalized patients have shown to develop dengue haemorrhagic fever (DHF), while 0.6% to 1.5% require admission to the intensive care units(2-4). As 70% of dengue infections occur in Asia, dengue causes a huge burden to resource-poor economies in developing countries(5). Although the recent case fatality rates in many countries have declined to <0.5% due to intense monitoring and meticulous fluid management, the case fatality rates are still around 2.6% in some countries such as India(6). Therefore, there is an urgent need to develop biomarkers which can identify patients who will develop severe disease and effective drugs to treat dengue.

Endothelial dysfunction leading to vascular leak in the hallmark of DHF(7). Plasma leakage leads to accumulation of fluid in pleural and peritoneal cavities, and when severe, it causes reduction of blood pressure leading in poor organ perfusion resulting in shock and organ dysfunction. Many inflammatory cytokines, lipid mediators and secretory virus protein NS1 has been shown to contribute to the vascular leakage(8-11). The dengue virus (DENV) has been shown to activate mast cells, and the vascular leak in dengue mouse models has been shown to be mast cell dependent(12). Mast cell stabilizing drugs such as cromolyn and

ketotifen and the leukotriene inhibitor montelukast, significantly reduced the vascular leak in dengue mouse models, implying their role in dengue pathogenesis.

We have previously shown that many inflammatory lipid mediators such as platelet activating factor (PAF) and secretory phospholipase A2 levels were higher in patients with DHF, and that endothelial dysfunction induced by dengue sera was inhibited by PAF-R blockers, in vitro, which also showed a trend towards a reduction in vascular leakage in patients with acute dengue(2, 9, 13). Leukotrienes are another group of inflammatory lipid mediators that are produced by the action of lipoxygenase enzymes on arachidonic acid substrates, and include LTB<sub>4</sub>, LTC<sub>4</sub>, LTD<sub>4</sub> and LTE<sub>4</sub> (14). These mediators are potent chemoattractants to neutrophils and eosinophils, and some are also known to increase vascular permeability and induce vascular leak (14, 15). LTE<sub>4</sub> specifically has been shown to induce vascular leak, specifically by contracting the endothelial cells in the post-capillary venules(16). Serum leukotriene B<sub>4</sub> levels were shown to be elevated in a small cohort of patients with acute dengue infection, when compared to healthy individuals and other febrile illnesses and correlated with inflammatory markers such as highly sensitive CRP(17). In vitro experiments have also shown that the DENV induced LTB<sub>4</sub> from neutrophils, suggesting that there could be multiple sources of leukotrienes in acute dengue infection. However, if leukotrienes correlate with clinical disease severity, viraemia and serostatus and the relationship with the onset of vascular leak in acute dengue has not been investigated.

Currently all individuals who have warning signs of possible severe disease such as persistent vomiting, abdominal pain, leucopenia along with thrombocytopenia are admitted to the hospital(18). However, only 25% to 34% of such patients would develop complications such as DHF and organ dysfunction(2, 4, 19). The onset of plasma leakage usually occurs during 3 to 6 days and lasts for 24 to 48 hours, which is known as the critical phase(7, 18). Those who do not develop vascular leak have a self-limiting illness known as dengue fever, and usually recover without any intervention, except if accompanied by bleeding manifestations. However, due to the absence of a reliable biomarker, all patients who are admitted should be closely monitored, several times a day, which is a huge burden in overcrowded hospital facilities with limited staff. Several potential biomarkers have been identified such as serum chymase, serotonin, VEGF and tryptase levels(20-23). However, it would be useful to evaluate a urinary biomarker to predict the development of DHF during early illness as it would user friendly.

Urinary LTE<sub>4</sub> has been shown to be a stable metabolite in urine and spot urine LTE<sub>4</sub> levels have been evaluated as a diagnostic marker of atopic asthma in pre-school children.(24) In this study we evaluated the levels of urinary LTE<sub>4</sub> and histamine in a large cohort of patients with varying severity of acute infection during early illness, their kinetics throughout the illness and also diurnal variations. We investigated the relationship between the urinary LTE<sub>4</sub> levels, with the onset of vascular leakage, viral loads and serostatus.

## Materials and Methods

### *Patients for analysis of LTE<sub>4</sub> levels in early illness*

120 adult patients with acute dengue infection were recruited from the National Institute of Infectious Diseases during the years 2018-2019, following informed written consent. The duration of illness at the time of recruitment and obtaining blood and urine samples was [?] 4 days of illness in 120 patients and between 5 to 6 days in 54 patients. The first day of illness was considered as the first day they developed fever. Any individual who had chronic liver disease, chronic renal disease and pregnant women were excluded from the study.

The patients were assessed several times a day for changes in blood pressure, urine output, presence of bleeding manifestations and possible leakage. Ultrasound scans were performed to determine the presence of fluid leakage in pleural and peritoneal cavities. All the clinical parameters (e.g. blood pressure, temperature, heart rate, pulse pressure and fluid leakage) and investigation results such as FBC, liver function tests, serum electrolytes were recorded throughout the course of illness. The severity of dengue infection was classified according to the 2011 WHO dengue diagnostic criteria(18). Accordingly, patients with a rise in haematocrit above [?] 20% of the baseline haematocrit or with clinical or ultrasound scan evidence of plasma leakage

were classified as having DHF. Based on this classification, in those recruited in [?]4 days of illness (n=120), 72 patients had DF and 48 DHF and those recruited between day 5 to 6 (n=54), 27 had DF and 27 had DHF. Nineteen healthy individuals who did not having any atopic illnesses (allergic rhinitis, asthma, food allergies or eczema), and who were not on antihistamines or steroids were recruited as healthy controls.

### **Patients for analysis of serial changes in LTE4 levels and diurnal variations**

In order to assess the kinetics of LTE4 throughout the course of illness, we recruited 48 patients with varying severity of acute dengue and obtained serial blood and urine samples daily in the morning (9am), throughout the course of illness. In addition, as we earlier found that there was a diurnal variation in platelet activating factor (PAF) in 2 cohorts of patients (9, 13), we further recruited 22 patients (14 who had DF and 8 with DHF), to assess possible diurnal changes in LTE4 levels in the morning (9 a.m.) and the afternoon (3 p.m.). We had to recruit a different cohort to explore the diurnal variation of LTE4 and viral loads as the same cohort of patients did not consent to be bled twice a day due to the frequent bleeding of these patients (four times a day), as a part of their dengue management.

### **Ethics approval**

Ethical approval was obtained by the Ethics Review Committee of the Faculty of Medical Sciences, University of Sri Jayewardenepura (Ethics application number: 12.15). All patients were recruited following written informed consent.

### **Quantification of urinary LTE4, histamine and creatinine**

Levels of LTE4 and histamine were measured in urine stored at -80°C, using leukotriene quantitative ELISA (Cayman Chemical, USA) and histamine quantitative ELISA (Abcam, UK) according to the manufacturer's instructions. Assays were performed in urine diluted at 1:5 ratio for assessment of leukotriene levels and undiluted urine for used for measurement of histamine. Urinary creatinine levels were measured in all patients and healthy individuals in order to normalize the urinary LTE4 and histamine levels using the urinary creatinine colorimetric assay (Cayman Chemical, USA). These assays were carried out and interpreted according to the manufacturer's instructions.

### **Determining Viral loads and the DENV serotypes**

Viral RNA from all serum samples were extracted using QIAamp Viral RNA Mini Kit (Qiagen, USA) according to manufacturer's instructions. Reverse transcription of the extracted viral RNA to cDNA was done using a high capacity reverse transcription kit (Applied biosystems, USA). To detect and quantify the DENV, a quantitative multiplex real time PCR was carried out as previously described (Fernando *et al.* , 2016), using the CDC real time oligonucleotide primers, and dual labeled probes for DENV 1-4 serotypes (Life technologies, USA). The reaction was performed for 20 seconds at 95°C for initial denaturation, followed by 40 cycles, 95°C at 3 seconds and 60°C at 30 seconds. The threshold cycle value (Ct) for each reaction was determined by manually setting the threshold limit. A multiplex method was optimized to quantify the four serotypes in a single reaction and viral quantification of unknown samples was performed using the standard curve.

### **Determining primary and secondary dengue**

Dengue antibody assays were performed in 77 patients, who had a duration of illness of more than 5 days, using a commercial capture-IgM and IgG Enzyme- Linked Immunosorbent Assay (ELISA) (Panbio, Australia). Results were interpreted according to the manufacturer's instructions. According to the WHO 2011 criteria, patients with an IgM: IgG ratio of >1.2 were classified as having a primary dengue infection, while patients with IgM: IgG ratios <1.2 were categorized under secondary dengue infection. Based on these criteria 26 (34%) had a primary dengue infection and 51(66%) had a secondary dengue infection.

### **Statistical analysis**

Statistical analysis was performed using Graph pad PRISM version 8. The differences in LTE4 in single

samples were done using the two tailed Mann-Whitney U-test and Kruskal-Wallis test. The degree of association between urinary LTE4 levels and viral loads, antibody levels and other laboratory tests was analyzed using Spearman correlation coefficient test. Changes in the LTE4 levels throughout the course of illness was compared using the Holm-Sidak method. Corrections for multiple comparisons were completed using the Holm-Sidak method and the significance value was set at 0.05 (alpha). A receiver-operator characteristic (ROC) curves showing the area under the curve (AUC) were generated to determine the discriminatory performance of LTE4 in predicting those who will develop DHF during early illness. The non-parametric Kruskal-Wallis (KW) test was used to analyze LTE4 levels in different age groups.

## Results

### Patient characteristics

A total of 120 patients with a duration of illness of day [?] 4 were included in this study out of which 72 individuals had DF and 48 proceeded to develop DHF based on the 2011 WHO classification of dengue disease severity (**Table 1**). Two patients who had DHF developed shock. All patients recovered and there were no fatalities. Six (8.3%) patients with DF and 7 (14.5%) patients with DHF had bleeding manifestations. In the patients with DF, four had vaginal bleeding and two had melena, whereas in the patients with DHF, one had melena and five had vaginal bleeding. Although 6 patients with DF had bleeding manifestations, none of them had evidence of fluid leakage and therefore, did not fulfill the criteria to be classified as DHF.

### Urinary LTE4 levels in patients with acute dengue

In patients with a duration of illness of [?] 4 days (n=120), the urinary LTE4 levels were significantly higher (p=0.004) in patients who proceed to develop DHF (median 1741, IQR 980.1-2,799 pg/mg creatinine) when compared to patients with DF (median 1178, IQR 592.6- 2,034 pg/mg creatinine)(**Fig 1**). Although the LTE4 levels in patients with DF was higher than in healthy individuals (median 706.6 pg/mg creatinine, IQR 535.3- 1639 pg/mg creatinine) this difference was not significant (p= 0.148). The urinary LTE4 levels were also significantly high (p=0.02) in patients with DHF (median 1755, IQR 1,102-2,875 pg/mg creatinine) on day 5 to 6 of illness compared to those with DF (median 1,263, IQR 729.9- 2,383 pg/mg creatinine) (**Fig 1**).

### Changes in urinary LTE4 based on serostatus, viral loads and infecting virus serotype

It was previously shown that patients with secondary dengue infection had higher serum chymase levels and it was shown that this is likely to be due to increased infection of mast cell and degranulation by the DENV in the presence of DENV antibodies in mouse models(20, 25). There was no significant difference (p = 0.25) in urinary LTE4 levels in patients with primary dengue (median 1242, IQR 654.9- 1671 pg/mg creatinine) compared to those with secondary dengue (median=1560, IQR 775.0- 2650pg/mg creatinine) (**Fig 2a**). However, patients with DHF during secondary dengue had significantly higher levels (p=0.02), than in those with DF.

There was no association between the viral loads and urinary LTE4 levels in either patients with DF (Spearman's r = -0.09, p = 0.46), or DHF (Spearman's r = 0.18, p = 0.27) (**Fig 2b**). Of the 120 patients recruited in the study during early illness of which the infecting DENV serotype was known, 20 was infected with DENV 1, 61 with DENV 2 and 11 with DENV 3 (**Fig 2c**). There was no significant difference in the urinary LTE4 levels in patients infected with different DENV serotypes (**Fig 2c**). There was no association of urinary LTE4 levels with the white cell counts, although weak but significant inverse correlation was seen with the platelet counts (Spearman r = -0.19, p = 0.04).

### Usefulness of LTE4 in predicting development of DHF in early illness

As urinary LTE4 levels were higher in patients who proceeded to develop DHF during early illness ([?] 4 days of illness), we sought to assess if urinary LTE4 could be used as a predictive marker of subsequent development of DHF in early illness. Receiver-operator characteristic (ROC) curves showing the area under the curve (AUC) were generated to determine the discriminatory performance of LTE4 for DHF in early

illness, which showed an AUC value of 0.67, with a 95% confidence interval of 0.57 and 0.76, which was significant ( $p=0.002$ )(**Figure 3**) .

### Kinetics of changes of LTE4 throughout the course of illness

LTE4 by itself has shown to cause endothelial dysfunction leading to vascular leakage(16) . Since our results showed that urinary LTE4 levels were significantly higher in patients with DHF, during early illness, we sought to investigate if LTE4 levels were highest during the febrile phase or the critical phase to further understand the possible contribution of LTE4 to disease pathogenesis. In order to study the kinetics of LTE4, we measured the urinary LTE4 levels in 25 patients with DF and 23 patients who developed DHF throughout the course of illness with urine samples taken at 9am in the morning. We found that the urinary LTE4 levels rose in patients with DHF from day 3 to 5 and remained high whereas there was no such rise from day 3 in patients with DF (**Fig 4a**) . The patients who developed vascular leak (those who developed DHF),entered the critical phase between day 4 and 5 of illness and the rise of LTE4 levels in these patients was when they entered the critical phase. Although the urinary LTE4 levels was high throughout the illness in patients with DHF compared to those with DF, this was not significant at any time point, probably due to the lower number of patients included in the serial sampling, which was likely not sufficiently powered to see changes of statistical significance.

We previously showed that levels of PAF showed a diurnal variation in two cohorts of patients with acute dengue(9, 13). Patients with DHF, had high PAF levels in the morning, which markedly reduced in the afternoon<sup>2</sup>. Therefore, in order to find out if similar changes were observed with LTE4, levels were measured in the morning (9am) and late afternoon (3pm), in 14 patients with DF and 8 patients with DHF. We found that in some patients while LTE4 levels fell towards the afternoon, in others the LTE4 levels were higher at 3pm (**Fig 4b**) . Such differences in urinary LTE4 levels were seen in both patients with DF and DHF (**Fig 4b**). Urinary LTE4 levels were higher in the afternoon samples in 71% (10/14) patients with DF and 50% (4/8) patients with DHF, when compared to the morning urinary LTE4 levels, but overall the timing differences were not significant.

In some patients, several fold changes in the viral loads were also seen between morning and afternoon samples in patients with both DF and DHF(**Fig 4c**) . Viral loads were higher in the afternoon samples in 38% (5/13) patients with DF and 57% (4/7) patients with DHF, when compared to the morning viral loads. However, these changes in viral loads did not reflect in the changes in urinary LTE4 levels. For instance, while the LTE4 level increased the afternoon samples in 14 patients, the viral loads only increased in 9 samples (**Fig 4c**) .

### Association of urinary LTE4 levels with age and gender in acute dengue

Of the 120 patients who were recruited during early illness ([?] 4 days of illness), 48 (40%) were females and 72 (60%) were males. There was no significant difference in the LTE4 levels between males and females ( $p = 0.343$ ) (**Fig 5a**) . However there was a significant positive correlation between urinary LTE4 levels and age (Spearman  $r = 0.20$  and  $p = 0.03$ ) (**Fig 5b**) . A significant difference ( $p=0.003$ ) was observed in the urine LTE4 levels in those who were [?] 25 years ( $n=55$ ), those who were 26 to 40 years ( $n=31$ ) and those who were [?] 41 years ( $n=33$ ) (**Fig 5c**) . However, the proportion of those who had DHF ( $n=20$ , 60.6%) was higher in those who were [?] 41 years, compared to those who were [?] 25 years ( $n=16$ , 29.1%), which could have accounted for these changes. (**Fig 5c**) .

### Urinary Histamine levels in patients with acute dengue

A study carried out in a small cohort of patients, who had severe dengue showed that 24-hour urine histamine was higher in patients with DHF compared to healthy individuals (Syenina A et al., 2015). Therefore, in order to understand the possible role of histamine in disease pathogenesis, we determined the urinary histamine levels in patients recruited [?] 4 days of illness ( $n=91$ ), between 5 to 6 days of illness ( $n=37$ ) and 29 healthy individuals. Of the 91 patients recruited [?] 4 days of illness, 52 had DF and 39 had DHF. In comparison to healthy individuals (median 0.22, IQR 0.07–0.76ng/mg creatinine), patients with DF (median

2.92, IQR 0.53–7.83ng/mg creatinine,) and those who proceeded to develop DHF (median 5.4, IQR 1.10–5.4ng/mg creatinine,  $p = 0.0001$ ) had significantly higher levels of urinary histamine ( $p < 0.0001$ ) (**Fig 6a**). Although patients with DHF had higher levels of urinary histamine compared to patients with DF it was not statistically significant ( $p = 0.31$ ) (**Fig 6a**). Although the urinary histamine levels were lower during day 5 to 6 in patients with DF (median 0.15, IQR 0.06 – 0.86ng/mg creatinine,  $p = 0.80$ ) compared to healthy individuals, the histamine levels of those with DHF was still high (median 0.29, IQR 0.05 – 1.12ng/mg creatinine). (**Fig 6a**).

There was no significant difference in urinary histamine levels in patients with primary and secondary dengue (**Fig 6b**) and there was no relationship with the viral loads (**Fig 6c**). The urinary histamine levels did not significantly correlate with urinary LTE4 levels in patients with DF (Spearman  $r = -0.08335$ ,  $p = 0.56$ ) or DHF (Spearman  $r = -0.2446$ ,  $p = 0.13$ ) (**Fig 6d**).

### Kinetics of changes of Histamine throughout the course of illness

In order to determine the changes in urinary histamine throughout the illness, we measured histamine in 16 patients DF and 16 patients with DHF throughout the course of illness (**Fig 7a**). In patients with both DF and in those who proceeded to develop DHF, urinary histamine levels gradually declined from illness day 3 onwards. We also investigated possible diurnal variation in urinary histamine levels in 9 patients with DF and 7 patients with DHF (**Fig 7b**). In patients with both DF ( $p = 0.004$ ) and DHF ( $p = 0.01$ ) the urinary histamine levels significantly decreased in the afternoon (3pm) samples compared to the morning samples, although there was wide inter-individual variation (**Fig 7b**). Similar diurnal variations were seen with serum viral loads in patients with both DF and DHF (**Fig 7c**).

### Association of urinary Histamine levels with age and gender in acute dengue

Of the 91 patients who were recruited during early illness ([?] 4 days of illness), 36 (40%) were females and 55 (60%) were males. There was no significant difference in the LTE4 levels between males and females ( $p = 0.78$ ) or any correlation between age and histamine levels in acute dengue.

### Discussion

In this study we show that urinary LTE4 levels were significantly higher in early illness in patients, who proceed to develop DHF. The LTE4 levels continued to be higher during later stages of illness (day 5 to 6), in patients with DF and DHF and the levels during later stages of illness in patients with DHF were higher than those of early illness. Although the levels of urinary LTE4 was significantly higher in those who proceeded to develop DHF during early illness, urinary LTE4 levels did not appear to perform well as a biomarker due to the low AUC values. This is possibly due to the wide diurnal variation seen in the LTE4 levels in patients with both DF and DHF. Diurnal variation in both urinary LTE4 and histamine levels have been previously observed in patients with asthma and in normal individuals, although no specific pattern was observed, as in this study(26). We too did not observe a consistent pattern in the changes of urinary LTE4 in the morning compared to the afternoon. This is in contrast with changes observed with PAF, with the levels always being high in the early morning levels, compared to the afternoon levels(9, 13). Interestingly, similar changes were observed with viral loads between morning and afternoon samples, with a 10-fold to 100-fold difference in some patients. Again, there was no particular pattern with the viral loads rising in some patients, while decreasing others and the changes in the viral loads did not show any relationship with the LTE4 or histamine levels.

Cysteinyl leukotrienes are synthesized from cells which possess LTC4 synthase, such as eosinophils, mast cells, basophils and macrophages(27). Many other enzymes act on the subsequent products LTC4, LTD4 and subsequently LTE4, of which the stable N-acetyl derivative is found in the urine(27). All these cells are readily infected by the DENV and are susceptible to enhanced infection and activation by the DENV in the presence of IgG antibodies which bind to the activating type of FcγRIIIA receptors(25, 28). Indeed it was shown that mast cells were significantly more activated in secondary dengue infections(12). Although LTE4 levels were not high in patients with secondary dengue infection, in this study, the levels were higher in those

with DHF due to secondary dengue compared to those with DF. However, our results showed that overall the LTE4 levels were higher very early in illness, irrespective of serostatus and the degree of serum viraemia. Therefore, LTE4 production appears to be enhanced very early during infection, and increasing in those who develop DHF during the critical phase, suggesting that the pathway may contribute to the vascular leak. Montelukast is a cysteinyl leukotriene receptor antagonist and is widely used to inhibit the action of leukotrienes in asthma and many other allergic diseases(29, 30). In dengue mouse models it was shown to reduce the extent of vascular leak(12). As montelukast is a relatively safe drug, it would be important to evaluate its efficacy in reducing dengue disease severity.

Mast cells are the main source of histamine although it can also be produced by basophils and the intestinal epithelium and other cells(31). Histamine has been shown to induce mast cells to release leukotrienes, cytokines and also increase vascular permeability(31). Although cross linking of the IgE bound to the high affinity FcεRI is the main trigger of histamine release from mast cells, complement components C3a, C5a and cytokines such as IL-33, IL-3, IL-18 and GM-CSF have been shown to induce synthesis and release(32). Although we found that histamine levels were significantly higher in patients with acute dengue, there was no difference in their levels in those with DF compared to those with DHF. In addition, the histamine levels fell in both patients with DF and DHF during the course of illness, which was in contrast to what was observed with urinary LTE4 levels. Interestingly, unlike LTE4 levels, the urinary histamine levels were always lower in the afternoon when compared to the morning, as seen with the variation of PAF(9, 13). We recently conducted a phase II, randomized, placebo controlled clinical trial with rupatadine to evaluate its efficacy in reducing vascular leak in acute dengue(2). Rupatadine significantly inhibited the effects of dengue sera on human endothelial cells lines by reducing the reduction in trans-endothelial resistance and a reduction in ZO-1 expression and also showed small but significant differences in the extent of fluid leakage and thrombocytopenia, when the drug was given early(2). Rupatadine is an antihistamine with PAF receptor antagonist effects(33). Therefore, it would be important to evaluate if some of the effects of rupatadine was also due to its antihistamine effects.

## Conclusions

We found that urinary LTE4 levels were significantly higher in early illness in patients, who proceed to develop DHF. The LTE4 levels continued to rise during the course of illness in patients with DHF, whereas the levels remained unchanged in those with DF. As there are cysteinyl leukotriene receptor antagonists available, it would be important to evaluate if these drugs could reduce dengue disease severity.

## Tables

Clinical Characteristics	DF (n=72)	DHF (n=48)
Vomiting	20 (27.8%)	19 (39.6%)
Abdominal pain	09 (12.5%)	14 (29.2%)
Arthralgia	54 (75%)	44 (91.6%)

Clinical Characteristics	DF (n=72)	DHF (n=48)
Myalgia	45 (62.5%)	39 (81.2%)
Diarrhoea	19 (26.4%)	22 (45.8%)
Bleeding manifestations	06 (8.3%)	07 (14.5%)
US scan evidence of fluid Leakage (pleural effusions or ascites)	00 (0.0%)	48 (100%)
Lowest platelet count		
<20,000cells/mm <sup>3</sup>	01 (1.4%)	23 (47.9%)
20,000-50,000	11 (15.3%)	21 (43.8%)
50,000-100,000	32 (44.4%)	04 (8.3%)
>100,000	28 (38.9%)	00 (0.0%)

**Table 1: Clinical and laboratory features of patients recruited for the study with [?]4 days of illness**

### Figure legends

**Figure 1: Urinary LTE4 levels in patients with acute dengue .** Urinary LTE4 levels were measured by quantitative ELISA, in healthy individuals (n= 19), in those with DF (n= 72) and those who progressed to develop DHF (n=48) with <4 days of illness and in patients with DF (n = 27) and DHF (n= 27) in 5 to 7<sup>th</sup> day of illness. The p values were calculated by the Mann-Whitney test. Error bars represent the median and IQR. \*P ;0.05, \*\*P<0.001, \*\*\* P<0.0001

**Figure 2 : Association of urinary LTE4 levels serostatus, viral loads and infecting virus serotype in patients with acute dengue .** Urinary LTE4 levels were measured in patients with DF (n=21) or DHF (n=05) due to primary infection or DF (n=20) or DHF (n=22) due to secondary infection (a), urinary LTE4 levels were correlated with viral loads in patients with DF and DHF. (b), and the differences in the urinary LTE4 levels were assessed in patients infected with different virus serotypes DENV1 (n=20), DENV2 (n=61) and DENV3 (n=11). The p values were calculated by the Mann-Whitney test and the correlation assessed by the Spearmans correlation. Error bars represent the median and IQR. \*P ;0.05, \*\*P<0.001, \*\*\* P<0.0001

**Figure 3: The usefulness of LTE4 as a predictive factor of DHF.**Receiver-operator characteristic (ROC) curves showing the area under the curve (AUC) were generated to determine the discriminatory performance of urinary LTE4 in predicting those who will develop DHF during early illness ([?] 4 days) in those who progressed to develop DHF (n=48) or DF (n= 72). Area under the curve AUC=0.66 and P = 0.0039.

**Figure 4: Kinetics and diurnal changes of urinary LTE4 .** Urinary LTE4 levels were measured daily from the day of admission to discharge in patients with DF (n=25) and DHF (n=23), throughout the course of illness. The blue lines represent DF and red DHF. Error bars represent standard error of mean (SEM) and mean (a). Urinary LTE4 levels (b) were measured in patients with DF (n= 14) and DHF (n=8) and serum viral loads were measured in patients with DF (n = 13) and DHF (n=7) (c).

**Figure 5: Association of urinary LTE4 levels with age and gender in acute dengue.** Urinary LTE4 levels in patients with acute dengue were compared between females (n=48) and males (n=72) (a), correlated with the age of the individuals by Spearmans correlation coefficient (b), and compared between different age groups; those [?] 25 years (n= 55), 26 to 40 years (n = 31) and [?] 41 years (n = 32) (c). The comparisons were done using the Mann-Whitney test and Kruskal-Wallis test. Error bars represent the median and IQR. \*\*P = ;0.01.

**Figure 6 : Urinary Histamine levels in acute dengue infection .** Urinary histamine levels were measured by quantitative ELISA, in healthy individuals (n= 29), in those with DF (n= 52) and those who progressed to develop DHF (n=39) with <4 days of illness and in patients with DF (n = 15) and DHF (n= 25) in 5 to 7<sup>th</sup> day of illness (a). The histamine levels were compared patients with DF (n=17) or

DHF (n=05) due to primary infection or DF (n=11) or DHF (n=25) due to secondary infection (b), were correlated with urinary LTE4 levels (c), correlated with the viral loads (d) The p values were calculated by the Mann-Whitney test and the correlations carried out by the Spearmans correlation. Error bars represent the median and IQR. \*\*\* P<0.0001

**Figure 7: Kinetics and diurnal changes of urinary histamine .** Urinary histamine levels were measured daily from the day of admission to discharge in patients with DF (n=16) and DHF (n=16), throughout the course of illness. The blue lines represent DF and red DHF. Error bars represent standard error of mean (SEM) and mean (a). Urinary histamine levels (b) were measured in patients with DF (n=19) and DHF (n=7) and serum viral loads were measured in patients with DF (n=8) and DHF (n=7) (c). \*P ≤0.05,
