Abstract

During geographical expansion of a species individual colonizers have to confront different ecological challenges, and the capacity of the species to broaden its range may depend on the total amount of adaptive genetic variation supplied by evolution. We set out to test whether the distribution of loci under selection along a contrasting environmental gradient can be turned into a model that accurately predicts a species' range. If positive, this may shed light on the genetic source of adaptive limits that shape range boundaries. We sampled five populations of the western Mediterranean lizard Psammodromus algirus that inhabit a noticeable environmental gradient of temperature and precipitation. We used 21 SNPs putatively under selection to correlate the genotypes of 95 individuals with environmental variation among their populations, using 1x1 km2 grid cells as sampling units. By extrapolating the resulting model to all possible combinations of alleles, we inferred the locations that were theoretically suitable for the species. The inferred distribution range overlapped to a large extent with the realized range of the species, including an accurate prediction of internal gaps and range borders. Our results suggest an adaptability threshold determined by the amount of genetic variation available that would be required to warrant adaptation beyond a certain limit of environmental variation. These results support the idea that the expansion of a species' range may be ultimately linked to the arising of new variants under selection.

Environmental association modelling with loci under divergent selection predicts the distribution range of a lizard

Abstract

During the historical building of a species range, individual colonizers have to confront different ecological challenges, and the capacity of the species to broaden its range may depend on the total amount of adaptive genetic variation supplied by evolution. We set out to increase our understanding of what defines a range and the role of underlying genetics by trying to predict an entire species' range from the geographical distribution of its genetic diversity under selection. We sampled five populations of the western Mediterranean lizard*Psammodromus algirus* that inhabit a noticeable environmental gradient of temperature and

precipitation. We correlated the genotypes of 95 individuals (18-20 individuals per population) for 21 SNPs putatively under selection with environmental scores on a bioclimatic gradient, using 1x1 km^2 grid cells as sampling units. By extrapolating the resulting model to all possible combinations of alleles, we inferred all the geographic cells that were theoretically suitable for a given amount of genetic variance under selection. The inferred distribution range overlapped to a large extent with the realized range of the species (77.46% of overlap), including an accurate prediction of internal gaps and range borders. Our results suggest an adaptability threshold determined by the amount of genetic variation available that would be required to warrant adaptation beyond a certain limit of environmental variation. These results support the idea that the expansion of a species' range can be ultimately linked to the arising of new variants under selection.

Introduction

Aside from limits set by dispersal barriers, distribution range borders are commonly assumed to be the result of the constraints imposed by the ecological requirements of species (either biotic or abiotic), as environmental gradients may change towards suboptimal conditions near range edges (Hutchinson 1957; Brown 2002). All in all, the factors that shape these distribution borders not due to dispersal barriers are ultimately linked to local adaptation dynamics; simply put, a species does not occur outside its distribution border because it is not adapted to the environmental conditions beyond it (Kirkpatrick and Barton 1997; Bridle and Vines 2007). However, the edge of a species' range is typically more abrupt than expected, given that environmental change towards suboptimal conditions or niche boundaries is usually gradual (Sexton et al. 2009). Moreover, all across their ranges species meet a range of conditions that is much greater than the environmental change that takes place at the edge of the range (Kirkpatrick and Barton 1997). To understand these seemingly arbitrary boundaries to range expansion, Haldane (1956) proposed gene 'swamping' as a center-border effect by which gene flow from central to marginal habitats causes maladaptation at the edges of the range, reducing population density and constraining range expansion. This dynamic pattern would jeopardize adaptation at the edge of the range even if the genetic variants that could promote range expansion are present in the genetic pool of a species, because gene swamping would hamper a rise in the frequencies of adaptive alleles at range limits (Haldane 1956). However, this hypothesis has been subject to continuous debate (Nosil and Crespi 2004; Sexton et al. 2011; Polechová 2018).

Another possibility is that range limits arise because a species has fully colonized the spatial projection of its ecological niche, in such way that niche expansion must precede range enlargement (Hutchinson 1957). In such cases, since niche expansion implies adaptation to more extreme conditions along one or more environmental gradients, this process is limited by the magnitude of the additive genetic variance associated with adaptation to these gradients (Lande and Shannon 2006). Conversely, if habitat and/or environmental suitability remains high at and beyond range boundaries, then dispersal constraints, gene swamping and/or marginal demographic effects could be defining the location and shape of distribution limits (Kirkpatrick and Barton 1997; Bridle and Vines 2007; Charlesworth 2009; Peterson 2011, Duncan et al. 2015). However, if the genetic variability required for range expansion is not available in the genetic pool of a species, gene swamping cannot be invoked to explain range limits (Polechova and Barton 2015, Polechova 2018). Evaluating these different hypotheses is thus crucial to understand the adaptive causes underlying the formation and shaping of range edges (Sexton et al. 2009; Lee-Yaw et al. 2018).

Landscape genomics approaches have boosted our understanding of how environmental variables drive the genetic dynamics of local adaptation (Hoban et al. 2016; Ahrens et al. 2018). These methods can be applied to model (and predict) potential range boundaries by looking at the shifts in allelic frequencies along environmental gradients (Eckert et al. 2008; Herrera and Bazaga 2008, Razgour et al. 2019). Thus, it is possible to explore what loci govern the adaptability of a species, and to model the suitability of certain genotypes to different habitats all over a species' range (i.e., environmental association analyses; Rellstab et al. 2015; Whitlock and Lotterhos 2015). However, describing correlations between genotypes and environmental gradients is only one part of the challenge, because some loci could show strong but spurious associations with environmental gradients due to population history rather than natural selection. Thus, it is also paramount to identify the loci underpinning local adaptation, since they make the fraction of genetic variation that is

2

relevant to explain an individual's ability to disperse to, and thrive in, new habitats (Dudaniec et al. 2018). Identifying these combinations of loci under selection is a prerequisite to understand the adaptive basis of the origin and maintenance of new populations and, therefore, the genetic dynamics that shape range boundaries (Hargreaves et al. 2014).

New populations of a species can be established either by 1) the arrival of individuals carrying genetic adaptations to that new site, or 2) the arrival of genetic variants that can recombine in situ to generate new locally adapted genotypes (Barton and Etheridge 2018). Discerning between these two possibilities is a hard challenge. In particular, the last scenario is controversial because it assumes that an individual is able to reproduce in a location to which it is not adapted. However, the potential to produce new genetic combinations increases with dispersal rate, by rising the probability that different (suboptimal) genotypes eventually co-occur at the same new habitats (Barton and Etheridge 2018; LaRue et al. 2018). Thus, study organisms with low dispersal rates should reduce the confounding effects of dispersion, allowing us to focus on local adaptation dynamics as responsible of expansion constraints (Lee-Yaw et al. 2018).

In this study, we integrate genomic data into the distribution modelling of a lacertid lizard species, the Large Psammodromus *Psammodromus algirus* , whose phylogeographical and ecological differentiation is well characterized (Carranza et al. 2006, Díaz et al. 2017, Llanos-Garrido et al. 2019). This lizard is widespread across the Western Mediterranean region, and its range encompasses contrasting environmental conditions, extending from northern Africa in the south to southwest France in the north, and from Portugal in the west to Tunisia in the east (Fig. 1A). We used 21 loci putatively under selection (hereafter outliers; Llanos-Garrido et al. 2019) to model distribution boundaries on the basis of five closely located central populations that cover a representative fraction of the environmental variation faced by *P. algirus* across its entire distribution range. These outlier SNPs were identified by two methods of outlier detection, one of them independent of population coancestry (an extension of the Lewontin–Krakauer test; Bonhomme et al. 2010) and the other one not (Bayescan v.2.1; Foll and Gaggiotti 2008). To model the distribution of *P. algirus* from these SNPs putatively under selection, we ran an environmental association analysis (Rellstab et al. 2015) with allelic variants at loci under selection as predictors, and we extrapolated, for all possible allelic combinations at those loci, the geographical locations with suitable environmental conditions. By doing so, we were able to infer not only an ecological niche model of the whole distribution range of the species, but also the genotypes that would potentially be adapted to each geographical grid cell within it. We assumed a simple model without center-border biases, and in which every genotype is able to reach every geographic cell. Also, we only used the (adaptive) genetic variation at those particular loci likely to be associated with environmental conditions, in such way that we could know whether actual range limits are linked to adaptability thresholds determined by the amount of additive genetic variance available for selection. This approach allowed us to test whether a species' distribution range can be explained by the genetic dynamics that shape local adaptation, without invoking demographic processes such as gene swamping or increased homozygosity near the edge of the range (Herrera and Bazaga 2008; Polechová et al. 2009).

Specifically, we aimed to answer the following questions: 1) Is it possible to infer an entire distribution range on the basis of a limited number of outlier loci? 2) How important are limitations to dispersal in defining a species' range limits? 3) Are there fewer genotypes adapted to marginal conditions than to core conditions? And 4) is there an adaptability threshold, determined by the availability of genetic variance under selection, that constrains the expansion of the range beyond its actual boundaries?

Materials and Methods

Study system

Psammodromus algirus is a ground-dwelling, heliothermic lizard from the Western Mediterranean region whose distribution range encompasses a wide variety of habitats, from arid shrublands to temperate forests (Díaz and Carrascal 1991). In the Iberian Peninsula, where *P. algirus* is the most abundant and widespread lizard species, climatic heterogeneity is mirrored by broad changes in vegetation patterns: forests dominate in the west of its range, whereas shrublands prevail in the east. The genetic diversity of the species is broadly

3

structured in two mtDNA lineages, eastern and western, which diverged ca. 3-3.5 mya (Carranza et al. 2006; Verdú-Ricoy et al. 2010). These lineages show some degree of ecologically-driven divergence, because eastern lizards typically display a striped dorsal pattern absent among western ones, and striped and unstriped phenotypes seem to be adaptively linked to crypsis to the predominant habitat where lizards live (Díaz et al. 2017).

We sampled 95 lizards in five populations along a broad environmental gradient in the center of the Iberian Peninsula (Fig. 1B). Three sampling sites housed populations of eastern mtDNA adscription: 1) Lerma (L; 42.058 ºN, -3.611 ºE; 900 m asl; N = 18), a fragmented mixed forest interspersed with grassland patches, 2) Aranjuez (A; 40.016 ºN, -3.586 ºE; 594 m asl; N = 20), a hot, dry site with a high cover of herbs and shrubs and no trees, and 3) Brihuega (B; 40.778 ºN, -2.911 ºE; 1,009 m asl; N = 18), a deciduous open forest with a mosaic of grassland and woodland patches. The two other sampling sites had populations of the western lineage: 4) El Pardo (P; 40.511 ºN, -3.755 ºE; 658 m asl; N = 19), a xeric, lowland evergreen forest, and 5) Navacerrada (N; 40.726 ºN, -4.023 ºE; 1,230 m asl; N = 20), a montane location covered by deciduous forest. Several particularities of these populations make them representative of a wide range of selective pressures gathered around the core of this species' range: 1) lizards from Lerma inhabit a very fragmented forest archipelago that resembles the typical habitat of western lizards (although they belong to the eastern lineage; see Díaz et al. 2005; Santos et al. 2008; Telleria et al. 2011; and Pérez-Tris et al. 2019 for further information about habitat fragmentation effects in this system); 2) Aranjuez lizards inhabit the typical hot and dry habitat of eastern lizards, and although this locality is very close to the western populations included in this study (El Pardo and Navacerrada), it receives very little gene flow from them (Díaz et al. 2017), so that its isolated condition promotes the accumulation of genetic divergence subject to selection (Llanos-Garrido et al. 2019); and 3) the two western populations (El Pardo and Navacerrada) are separated by a significant altitudinal gradient, and although lizards from both populations show little genetic differentiation (Díaz et al. 2017), they differ in important phenotypic traits such as escape tactics, sexual dimorphism, sexual ornaments, ectoparasite loads and other life history traits (Iraeta et al. 2006, 2010, 2011; Llanos-Garrido et al. 2017).

Outlier analyses

The 21 loci under selection used in this study were detected by two different outlier search analyses conducted in a previous study (Llanos-Garrido et al. 2019), one of them independent of population coancestry (an extension of the Lewontin–Krakauer test; Bonhomme et al. 2010) and the other one not (Bayescan v.2.1; Foll and Gaggiotti 2008).

The outlier analysis performed with Bayescan detected 12 outlier loci with $\alpha > 0$ ($0.97 < \alpha < 1.35$) and q < 0.05, while the FLK analysis identified nine additional loci with $p < 0.001$, none of which was previously detected by Bayescan. An MDS analysis performed elsewhere with these 21 SNPs putatively under selection, placed sampled populations along a first major axis that recovered the same pattern of differentiation observed for mtDNA and for some relevant phenotypic traits (Llanos-Garrido et al., 2019). Moreover, these phenotypes were interpreted as adaptive after a process of ecologically-driven divergence in a much wider sample (Díaz et al., 2017). Thus, despite the fact that these outliers could not be the genetic basis of adaptive phenotypes, they showed a genetic differentiation that mirrors local adaptation to the environmental conditions at sampled populations.

Quantification of environmental variation

To quantify environmental variation all over the potential range of the species, we selected an area that included its actual distribution range (based on Bons and Geniez 1996 [for north-west Africa], Pleguezuelos 1997 [for the Iberian Peninsula] and IUCN web [for the rest of north Africa]) plus a 450-850 km wide perimeter belt around it (width variation depended on the distance from the edges of a non-quadrilateral range to the rectangle that was used to set the subsequent inference models). Within this area, we used data from the Bioclim 2.0 dataset (cell resolution = 1x1 km; Booth et al. 2014) to compute the score of each cell on a principal component analysis that combined all Bioclim environmental variables using R core

4

(R Core Team, 2013). This PCA yielded a single principal axis that opposed hot areas with low precipitation to temperate ones with high precipitation (Fig. 1B).

Environmental Association Analysis (EAA)

Environmental values (dependent variable for EAA models) were assigned to the 1x1 km grid cells where individuals had been sampled, using QGIS v2.18.16 (QGIS Delopment Team 2015) and a layer of PCA-scores within polygons defined by sampling locations. The genotypes for each loci (independent variables for EAA models) were recoded as 0, 1 or 2 depending on whether they were homozygous for the reference allele, heterozygous or homozygous for the alternative allele, respectively. As we pruned the SNP dataset by linkage disequilibrium, we avoided including any collinear predictors in the models.

Our EAA was constrained by the fact that the 95 individuals genotyped belonged to only five different populations (18-20 individuals per population). While this ensures a sufficient characterization of genetic variation within populations, it leads to unavoidable pseudoreplication of environmental data (and, depending on the extent of genetic differentiation and aggregation, also of genetic data). To make sure that this problem did not affect our conclusions, we used four randomization approaches, with the same model selection steps applied to each of them, so that they could be compared.

Firstly, we based our EAA on 1,000 random assignments of genotypes within populations to 1x1 km sampled grid cells (hereafter intra-population randomization). Given that environmental variation is several orders of magnitude larger among than within populations (97.6 % of the variance in PCA scores explained by population adscription), we chose to highlight the among-populations component of the models by assuming that all genotypes could occupy every grid cell within the geographical boundaries of their own population (which were determined by the discontinuous distribution of suitable habitat). This is more realistic than assuming a large component of genotype-environment covariation at a local, within-population scale. Moreover, the genetic component of such covariation could not be detected by our methods of outlier detection, which were specifically designed to search for genetic divergence among populations. Our set of 1,000 intra-population randomizations should therefore capture the actual pattern of genotypic and environmental covariation at the scale of the sampled gradient.

Secondly, we randomized 1,000 times the geographical grid cell assigned to each genotype without taking into account its population (hereafter inter-population randomization). This allowed us to produce a null hypothesis of no association between genotypic and environmental variation, but which takes into account the fact that environmental values are geographically structured by population of origin (and thus pseudoreplicated).

Thirdly, we used a randomized set of genetic data to control for the potential effects of genetic structure among populations and genetic aggregation within them (hereafter randomization by neutral loci). For that purpose, we constructed 1,000 new sets by randomly selecting 21 loci from each genotype (i.e. the number of detected outliers out of 6,421 SNP) but without taking into account whether they were characterized as outliers or not. This was done to account for the fact that neutral genetic variation (randomly selected SNPs) is expected to have the same degree of aggregation than variation under selection (outliers). However, while we should expect that at least a fraction of the genetic variation subject to selection should be correlated with environmental variation, the opposite is true for the neutral differentiation of populations.

Finally, we were aware that outlier analyses should effectively sort through the randomized SNP databases to identify those that explain the greatest variance among 'populations' (or subgroups). The projection of that variance into environmental PC-space could in turn draw some shape around the five sampled populations' environments that would be considered as suitable habitat, perhaps leading to significant genotype-environment associations. Because of that reason, the outlier selection step needs to be incorporated into our attempts to identify null expectations. To this end, our fourth randomization approach permuted the 6,421-SNP dataset and reran all the analysis from the outlier detection step onwards (hereafter complete randomization). We randomly assigned genotypes for all the 6,421 SNPs to individuals and ran Bayescan to detect outliers putatively under selection with the same methods we used with real data. Then we took the top 21 outlier SNPs to conduct genotype-environment association models and predict the species' range.

If the environmental signal of the SNPs generated by these simulations (and, as a consequence, expected by pure chance) is still smaller than that of real data, this must be interpreted as evidence that the SNPs selected by our EAA are not only correlated with the environmental gradient portrayed by our sampling populations, but also that they provide reasonably good proxies of genetic differentiation involved in local adaptation. We did not repeat the FLK extension test with this dataset because no significant phylogenetic (i.e. among-population) patterning is expected in a genetic dataset where genotypes are randomly assigned to individuals (and hence to populations). We performed 500 complete randomization tests instead of 1,000 due to computational limitations.

We performed a backward stepwise multiple regression analysis with each randomized data set (N = 3,500 EAAs in total), with SNPs as predictors and environmental scores as the dependent variable using *lm* function in R core. By doing this, we obtained a distribution of adjusted R^2 estimates and p-values for each set of randomizations. Final model building was achieved by considering the mean p-values of partial correlations calculated for all the datasets obtained with the intra-population randomization strategy. In each step, we removed all SNPs with a mean p-value > 0.5 (calculated from the p-values of all randomized datasets), and we recalculated all partial correlations with the remaining SNPs. In the last step, when all remaining markers had mean p-values < 0.5 (the mean number of SNPs removed in this step was 14 in intra-population randomizations, 18 in inter-population randomizations, 10.83 in randomizations by neutral loci, and 11.30 in complete randomizations), we removed all SNPs with mean p-values > 0.05. Our final model (genotype-environment association model, or GEAM) was built with the mean intercept and mean beta values of the remaining SNPs.

Range inference

To infer the distribution range of the species, we followed a two-step procedure. Firstly, we included all the geographical cells that presented the same environmental scores as the sampled populations (predicted range #1). This first approach provides a baseline prediction with no genetic information that can be used to quantify the improvement in predictive ability supplied by GEAM. Secondly, we extrapolated such GEAM to all possible combinations of alleles for the outlier loci significantly associated with environment (i.e., all possible genotypes under selection), so that we could predict all environmental values that were suitable for at least one genotype. By fulfilling all grid cells with those environmental values, we could extrapolate our prediction to the overall distribution range of the species. Finally, we removed from the inferred range a few disconnected patches (in central France, coastal Italy, and the Mediterranean islands) that were too far from the main distribution range of *P. algirus* (>8 km from the nearest inferred distribution limit, which was the largest distance between adjacent but disconnected patches within the inferred range), whose low dispersal rate (Santos et al. 2009) is supported by the fact that genetic differentiation can be detected even among forest fragments separated by 350 m of unsuitable arable land (Pérez-Tris et al. 2019). This produced our second (and final) inferred distribution range (predicted range #2). The extent of overlap between real and predicted distribution ranges was estimated using QGIS v2.18.16 (QGIS Development Team 2018).

The delineation of a real distribution range that could be compared with our inferences #1 and #2 was based on two previously published atlases: Bons and Geniez (1996) for north-west Africa, and Pleguezuelos (1997) for the Iberian Peninsula. To make such delineation as reproducible as possible, we digitalized these previous maps to get a grid of 10x10 km geographical cells, which was the original scale in the atlases. We subsequently added all the areas devoid of lizards, but embedded within the previous range, that were tagged with an artificial land use in the Corine database (European Environment Agency under Copernicus program, 2018). This was done to correct for the fact that absences from such areas should be attributed to land use (unsuitable for *P. algirus*) and not to the environmental variables included in our model. On the other hand, our inferred ranges were based on environmental variation measured across a grid of 1x1 km geographical cells, because a scale of 10x10 km cells would have been too rough to properly model the distribution range of the species. Thus, and for the sole purpose of estimating the accuracy of our inferences using a criterion as similar as possible to the one used in the atlases, we lowered their resolution by including all 10x10 km grid cells with at least 25% of its surface corresponding to inferred presences.

6

Results

Environmental Association Analysis

The PCA with all Bioclim environmental variables (N = 19 variables) yielded a single principal component (eigenvalue = 0.679) that retained four variables using the scree plot criterion: annual mean temperature (BIO1), max temperature of the warmest month (BIO5), mean temperature of the warmest quarter (BIO10), and annual precipitation (BIO12). Thereby, this component defined a bioclimatic gradient with a hot and dry extreme in the area occupied by the Sahara desert (highest values) and a temperate and wet extreme in northwestern Spain (lowest values; Fig. 1B).

A vast majority of inter-population randomizations and of randomizations by neutral loci resulted in non-significant models (Fig. 2). Mean adjusted R^2 for the random assignment of genotypes to populations (inter-population randomization) was 0.002 (SD = 0.038, range = 0 - 0.199), with a mean p-value of 0.487 (SD = 0.292, range = 0.0004 - 1); only 6% of the 1,000 randomized datasets yielded significant results. Mean adjusted R^2 for randomization by neutral loci (i.e. random within-population selection of SNPs, either outliers or not) was 0.002 (SD = 0.105, range = 0 - 0.324), with a mean p-value of 0.494; SD = 0.296, range = 0.001- 1); only 5.6 % of the datasets yielded significant models. In the case of the complete randomizations (i.e. fully permuted SNP datasets prior to outlier analysis), mean adjusted R^2 was 0.047 (SD = 0.092, range = 0 - 0.788), with a mean p-value of 0.616 (SD = 0.451, range = 10^{-7} - 1).

Datasets built by intra-population randomization produced highly significant models (mean adjusted R^2 = 0.646 ± 0.007, range = 0.623 - 0.670; mean p-value ± SD =3.5 x 10^{-17}± 2.8 x 10^{-17}, range = 2.02 x 10^{-18}– 2.93 x 10^{-16}; Fig. 2). Only 2 out of the 500 complete randomizations yielded a model that explained more environmental variability than those built with intra-population randomized datasets. Thus, the environmental association models including the SNPs under selection (intra-population randomization: mean R^2 = 0.646) had on average between one and three orders of magnitude more predictive power than those built with the other three randomization strategies (mean R^2 = 0.002, 0.002, and 0.047, for inter-population, by neutral loci, and complete randomizations, respectively). The final GEAM included four SNPs (all but one detected by FLK) with significant partial correlations whose final coefficients and p-values were computed by calculating their means across all intra-population randomized datasets (all but one detected by FLK; Table 1).

Range inference

Predicted range #1 allowed to forecast 40.09% of the species' range, while 15.12% of such predicted range fell outside real range limits (Fig. 3 and Fig. 4).) Predicted range #2 (i.e. the range inferred by extrapolating GEAM to include all grid cells suitable for any possible combination of alleles at the four loci that significantly correlated with environmental variables) was similar to the real species' range. All grid cells in predicted range #1 were included in predicted range #2, accounting for 50.45% of its total amount. In turn, predicted range #2 captured 77.46% of the actual distribution of *P. algirus* , with 17.27% of inferred presences beyond real range limits. The 22.54% fraction of the real distribution range unpredicted by GEAM mostly corresponded to the northwest corner of the range, as well as to a large number of small predicted gaps within it. Nevertheless, predicted range #2 accurately reflected not only the northern and southern edges of the real distribution range, but also many of the gaps within it, both in northwest Africa (i.e. far from the sampled populations) and in many Iberian mountain ranges (Fig. 3 and Fig. 4).

Because complete randomizations provided the most reliable null hypothesis for EAAs, we used them to infer the species range following the same procedure as described above. We ran a different EAA per fully randomized dataset because each of them included a different set of randomly generated 'outliers' (i.e. SNPs putatively under selection). The mean percentage of inferred range was 41.39% (SD = 4.799, range = 40.09 - 81.27), roughly equivalent to predicted range #1 but smaller than predicted range #2. Of the 500 complete randomization EAAs, only one (P = 0.002, Fig. 5) was able to infer a larger proportion of the species range (80.91%) than predicted range #2 (77.46%), but this was at the cost of a large proportion of inferred presences beyond real range limits (65.02%, vs. 17.27% for predicted range #2).

7

Discussion

Extrapolating genotype-environment association analyses to all possible combinations of alleles at a few outlier loci (i.e. supposed to be locally adaptive) allowed us to explore how much environmental diversity could be exploited by a given amount of genetic variation. This, in turn, revealed an adaptability threshold that might be ultimately defining the distribution boundaries of *P. algirus* . Thus, our successful inference of a species' range (77.46% of the actual species' range) from the geographical distribution of a few adaptive loci (N=4) uncovered the role of genotypic inter-individual variation in shaping a species' distribution range. Our approach should therefore provide compelling evidence of how the genetic dynamics of local adaptation underlie distribution patterns.

Environmental Association Analysis

Our intra-population randomization approach showed that the predictive power of GEAM was much larger than expected by chance. Such high predictive power was based on the genetic diversity found in five closely-located populations with geographical distances that were not correlated with either genetic or environmental distances (Llanos-Garrido et al. 2019). Yet, a small number of inter-population randomizations and randomizations by neutral loci also yielded significant models, as expected from a certain degree of environmental pseudoreplication and genetic aggregation in our data. However, the rate of significance was close to 5%, i.e. the conventional level of type I error rate for significance in statistical tests. On the other hand, our complete randomization approach, which included the critical outlier selection step, produced a relatively large number of significant models (25%, still much lower than the 100% obtained by the 'correct' intra-population approach). This confirmed that outlier analyses were effectively able to sort through the randomized SNP databases identifying those that explain the greatest variance among arbitrary subgroups, in such way that the projection of that genetic variance into the environmental PC-space around the five sampled populations resulted into significant association models. However, the environmental signal of these randomly genotyped SNPs was significantly smaller than that of real data. This supports the idea that the particular SNPs selected by our EAA could be good proxies for the genetic variability that is involved in local adaptation to different environmental conditions at each population.. In addition, given the low standard error of parameter estimates (Table 1), our final genotype-environment association model should be regarded as robust.

Range inference accuracy

Our approach combines the advantages of correlational and mechanistic distribution models (Holt 2009, Kearney and Porter 2009), because it relies on genotype-environment correlations based on the geographical distribution of field-captured individuals, but deals with SNPs putatively under selection that should be ultimately correlated with functional differences in morphology, physiology, and/or behavior (see also Brown et al. 2016, Razgour et al. 2019). This should allow us to enlarge the scale of our analysis to the species level (Buckley 2010), because the extrapolation of our results to all possible allele combinations at loci under selection should cover a much wider range of adaptive phenotypic variation than the one revealed by the physiological measurements of a restricted sample of individuals or populations, and (more importantly) by a priori decisions about what traits may be adaptive across an entire species' range. The only assumption behind this assertion is that all allelic combinations are actually plausible, as it should be expected if loci are correctly pruned by linkage disequilibrium. Moreover, as long as local adaptation leads to a heterogeneous distribution of the genotypes adapted to different parts of the range, our GEAM should be more realistic than mechanistic models, because such models are based on physiological measurements of individuals, and these may lack the specific adaptations required to thrive in specific habitats different from their own (such as the ones that determine range boundaries; Svardal et al. 2015, Brown et al. 2016, Razgour et al. 2019). However, the primary aim of this study is not to propose a new approach to simply infer species range (as there are many others more appropriate for this task), but to unveil the potential role of genetic variability as a major driver of range shape. Thus, the accuracy of this approach is only a symptom of the importance of such role, as the underlying model was built on the sole basis of the geographical distribution of SNPs under divergent selection.

8

Genotype-based range inference was especially accurate at the southern edge of the species' range, including a precise delimitation of range gaps in Morocco, where detailed chorological information is available (Bons and Geniez, 1996). However, we could not test the accuracy of our model for the rest of North Africa due to the lack of detailed distribution maps of *Psammodromus algirus* in this area. The only information about these locations was obtained from the IUCN Red List database (which does not provide data about within-range gaps) and the GBIF database (which has only 33 records distributed among 16 locations in this area [Fig. 1A], all of which except one were predicted by our model). Nevertheless, the distribution borders suggested by these databases were accurately predicted by our range inference.

Regarding northern boundaries in the Iberian Peninsula, where detailed data on the presence of *P. algirus* is also available (Pleguezuelos 1997), we did not recover the presence of the species in a relatively large NW area where lizard populations do occur, inhabiting suitable habitat patches near the cool, humid end of the tested environmental gradient. Across southern France, the real distribution range of the species does not exceed the Rhône River delta, a possible geographical barrier which could not be predicted by our method of range inference (see Carranza et al. 2006 for an explanation about how and when the species crossed another important, potential geographical barrier, namely the Strait of Gibraltar). However, in the Iberian Peninsula our model successfully recovered the central and eastern parts of the northern range boundary, as well as several within-range gaps associated with mountain ranges (around central plateaus and river valleys) and arid regions in south eastern Spain.

The asymmetry in accuracy when predicting northern vs. southern edges could be explained if our outlier analyses failed to capture all the genetic variation under selection that is associated with such gradient (see below). Another possible explanation is that the relative role of climatic variables in determining northern vs. southern edges of the species' range could be asymmetric (Cunningham et al 2015). Ectotherms tend to show this asymmetric patterns by underfilling their potential range at the southern/warmer edge while overfilling it at the northern/colder one (Sunday et al. 2012). However, this is not the case of *P. algirus* , because we did not predict any suitable habitat beyond the actual boundaries of the species' range, but an underfilling at its northern edge. Simply put, it seems that *P. algirus* is able to overcome the predicted cold constraint, even when previous studies have found that cold tolerance is the most limiting climatic factor for range expansion in ectotherms (St Clair and Gregory 1990, Sunday et al 2014). Independently of the biotic or abiotic nature of that unknown northern constraint, the resulting inferred range would exceed the actual border, whereas the opposite is true for our model (Fig. 3 and Fig. 4). Thus, it seems that some unknown variables, unrelated to either temperature or humidity, may be enabling the occurrence of *P. algirus* beyond our predicted northern boundaries (Guisan et al. 2006, Pearman et al. 2010, Wisz et al. 2013).

The role of niche boundaries and dispersal limitations in shaping range limits

The accuracy of our prediction of range limits suggests that they are revealing ecological niche boundaries to some extent. If other environmental factors (e.g. lack of prey or presence of competitors, predators or parasites) had been constraining range expansions, our inferred range would have extended beyond real range boundaries, and realized range edges would be explained by the existence of limitations to expansion before fulfilling all cells within the spatial projection of the species' niche (Holt 2003, Soberón and Peterson 2005, Holt 2009). In fact, this happened only in the northeastern border of the range, where GEAM predicted the presence of *P. algirus* beyond the barrier imposed by the Rhône River delta (niche boundaries would actually allow the species to reach Italy).

Also, our results point to an apparent lack of demographical center-border effects such as gene swamping or increased homozygosity near the edge of the range (Herrera and Bazaga 2008; Polechová et al. 2009; Pironon et al. 2017). If these processes were acting, they would be limiting the persistence of marginal populations near range boundaries, and we would systematically infer false positives beyond range limits (Case and Taper 2000; Bridle and Vines 2007; Lee-Yaw et al. 2018). However, this line of reasoning may be wrong, given the likely polygenic nature of adaptations to temperature and humidity (e.g. Rodríguez et al. 2017), if our approach had missed many of the small-effect variants that contribute to such adaptations; these variants should be relatively prone to gene swamping, showing lower core-margin differentiation that

9

the one we inferred (Lenormand 2002, Yeaman 2015). In that case, both allele fixation at a small number of major-effect loci (either the ones included in our model or others with similar differentiation patterns), and gene swamping at a large number of small-effect loci not included in our model, could explain the shape of range limits. In fact, we did wrongly infer a relatively large inland area of false positives on the northern side of the Pyrenees (Fig. 3 and Fig. 4), which could thus be interpreted as consistent with the hypothesis of gene swamping. However, this area was suitable for a small number of genotypes (< 3 out of 46), so that another plausible explanation for these false positives is the low probability that the few genotypes that could be adapted to these unoccupied areas were available in nearby marginal populations (Pujol et al. 2009; Dawson et al. 2010; Barton and Etheridge 2018).

The dispersal ability of the genotypes arising at range margins could play an important role in the colonization of new areas beyond range limits (Simmons and Thomas 2004; Hardie and Hutchings 2010). In our system, for example, the range of *P. algirus* would extend ca. 13% beyond its eastern European border if lizards were able to disperse across the Rhône River and no other factors were constraining its expansion. Furthermore, genetic diversity would be fostered by greater dispersion abilities (Duckworth 2008), which should facilitate the co-occurrence of adaptive allele combinations at range margins. For instance, the expansion of these small terrestrial ectotherms towards suitable areas north of the Pyrenees (false positives in our model) could be constrained by the synergistic effects of low dispersal rates and a low probability of finding adapted genotypes at nearby marginal populations. To clarify the relative role of dispersal ability vs. other possible constraints in the colonization of new areas beyond range limits (see above), our genotype-based modelling approach could be applied to species showing different dispersal abilities (Sanford et al. 2006; Dawson et al. 2010), or we could perform transplant experiments beyond range limits (i.e. manipulating species' dispersal abilities; Hargreaves et al. 2014). By doing this, we should be able to discern between the role of dispersal ability *per se* and the genetic contribution of pre-adapted genotypes arising (or not) at marginal populations (Bridle and Vines 2007; Sexton et al. 2009; Phillipsen et al. 2015).

Number of adapted genotypes per cell across the species' range

Besides the general pattern by which fewer genotypes were adapted to range boundaries than to core areas, we found two distinct scenarios within the Iberian Peninsula (Fig. 6). On the one hand, in the northern half of the peninsula there were many areas suitable for a high number of genotypes. In such context, there is a high probability of finding the few genotypes that are adapted to the challenging environmental conditions characteristic of northern boundaries, which should facilitate the establishment of the marginal populations that shape the corresponding edge (Kawecki 2008; Hardie and Hutchings 2010; Halbritter et al. 2015). Conversely, most of the southern half of Iberia seemed to be suitable only for a small number of genotypes, despite the fact that *P. algirus* is abundant in this area. However, several small areas locally suitable for many genotypes were interspersed all across the region. Such areas could therefore play an important role as sources of specific genetic diversity adapted to the demanding, singular environments that surround them (Holt and Keitt 2005; Sagarin et al. 2006). The genotyping of populations that inhabit demanding environments, suitable for a small number of allele combinations, would be crucial to sustain this assertion (Eckert et al. 2008; Gallet et al. 2018). Similarly, a model simulating the intensity of selection in both sources and sinks of genetic diversity should be useful to test whether the genetic variants adapted to demanding environments arise with higher probability in source populations with more relaxed selection regimes (Alleaume-Benharira et al. 2006).

Adaptability thresholds constrain range limits

Our results suggest that species' ranges are determined by the maximum possible span of environmental variation to which adaptive genetic variants are suited. As a consequence, range expansions should be constrained by adaptability thresholds. In our system, it seems that the environmental range to which *P. algirus* is adapted is ultimately linked to the amount of genetic variance under selection associated to a specific bioclimatic gradient. If positive, a range expansion promoted by adaptations towards more extreme environments should entail the selection of new genetic variants. Moreover, such range expansion would require that the effect of the new adaptive mutations is additive with respect to the ones that define the adaptability

threshold (Soberón and Peterson 2005, Polechová and Barton 2015, Polechová 2018). Whilst our results support this line of reasoning, further theoretical exploration is needed to uncover the hypothesized positive relationship between the magnitude of the increment in environmentally correlated additive genetic variance, and the extent of range expansion that can be achieved (Angert et al. 2008; Polechová et al. 2009).

Overall, we have shown that inferring species' ranges from the geographical distribution of SNPs under selection can be not only very accurate, but also informative about the genetic dynamics that underlie local adaptation all over a species' range. Our results suggest that the amount of genetic variability subject to selection is a determinant of the location and shape of range boundaries. This conclusion sheds light on the key processes that determine the configuration of distribution ranges, putting forward the importance of inherent limits to adaptation as an ultimate explanation for the evolution of their shape and boundaries (Connallon and Sgrò 2018).

Table 1. Parameter estimates for the regression coefficients of the SNPs under selection that entered the final model (GEAM).

	Parameter estimate $\pm$ SD (min, max)	P-value $\pm$ SD (min, max)
Intercept	- 3.630 $\pm$ 0.033 (- 3.739, - 3.539)	$2.42 \times 10^{-22} \pm 2.03 \times 10^{-22}$ (1.08×10^{-23}, 1.92×10^{-21})
SNP1	+ 0.605 $\pm$ 0.012 (0.567, 0.642)	$3.31 \times 10^{-7} \pm 1.85 \times 10^{-7}$ (6.62×10^{-8}, 1.46×10^{-6})
SNP2	+ 0.488 $\pm$ 0.019 (0.430, 0.551)	$5.55 \times 10^{-4} \pm 2.66 \times 10^{-4}$ (1.01×10^{-4}, 1.71×10^{-3})
SNP3	+ 0.347 $\pm$ 0.011 (0.315, 0.385)	$3.87 \times 10^{-4} \pm 1.78 \times 10^{-4}$ (7.31×10^{-5}, 1.49×10^{-3})
SNP4	+ 0.366 $\pm$ 0.010 (0.328, 0.396)	$2.81 \times 10^{-4} \pm 1.03 \times 10^{-4}$ (7.41×10^{-5}, 8.68×10^{-4})

Figure legends

Figure 1. A) Known distribution range of *Psammodromus algirus* (based on Bons and Geniez 1996 [northwest Africa] and Pleguezuelos 1997 [Iberian Peninsula]). The gaps within the range that correspond to artificial land uses according to Corine database wereconsidered as presences when embedded within the range. A question mark is placed where the species is known to inhabit but there is no accurate information about its distribution (27 presences scattered all over North Africa; grey squares in the figure). The discontinuous line defines the assumed southern edge of the distribution range according to IUCN. B) Bioclimatic gradient defined by the environmental PCA for all the western Mediterranean region (potential distribution range of *P. algirus*). Black circles mark the location of the sampled populations (L = Lerma, B = Brihuega, N = Navacerrada, P = El Pardo, and A = Aranjuez). On the right, the location of these populations and range edges (C/W = coldest/wettest, W/D = warmest/driest) within the environmental gradient from a single PC axis that was defined by using the scree plot criterion.

Figure 2. Distribution of adjusted R^2 values for regression models obtained with four different randomized datasets (see text for details).

Figure 3. Inferred distribution range. In dark green, predicted range #1 (grid cells with the same environmental scores than the sampled populations); and in clear green, predicted range #2 (inferred by extrapolating GEAM to any possible combination of alleles at the loci included in the final model). All cells within predicted range #1 were also included in range #2. Areas beyond 8 km of the continuum inferred range were removed (see text).

Figure 4. Inferred distribution ranges #1 (cells with same environmental values than sampling locations; A) and #2 (cells that were inferred to be suitable for any possible combination of alleles at the loci included in our GEAM; B) at the resolution scale that was comparable with previously published ranges.

Figure 5. Distribution of the proportion of the actual species' range that was inferred by completely randomized datasets incorporating the outlier selection step (see text for details). The proportion of range inferred by extrapolation of GEAM is marked with an arrow.

Figure 6. Heatmap representing the number of adapted genotypes per grid cell according to our GEAM.
