

22 **Abstract (150 words)**

23 Flash flooding is one of the most damaging weather types, yet it remains challenging to
24 quantify its severity. We propose a novel development – the Flashiness-Intensity-Duration-
25 Frequency (F-IDF) curve – to quantify and spatially analyze flash flood intensity based on the
26 frequency and duration of the event. As a proof-of-concept, we mapped Contiguous US
27 (CONUS)-wide F-IDF values at 3,722 stream gage locations and explored their relations with 59
28 basin attributes. It is found that (1) Climatological precipitation amounts exhibit the most
29 positive correlation with flashiness while a basin’s drainage area is the most negatively
30 correlated; (2) Correlation of flashiness with basin attributes decreases with increasing F-IDF
31 return periods and shorter event durations. Both aspects are attributable to the rainfall signal
32 overwhelming the underlying basin attributes as the intensities become more extreme. This new
33 term can have implications for hydrology, especially for hydrologic modelers, decision-makers,
34 and emergency responders.

35
36 **Plain Language Summary**

37 Flash floods are among the most devastating natural hazard types that can cause severe
38 property damage and loss of life. However, it's challenging to measure and quantify the severity.
39 This study proposes a new way of quantifying flash flood intensity using a newly developed
40 Flashiness-Intensity-Duration-Frequency (F-IDF) curve. It links flash flood severity with how
41 often they happen and how long they last. We mapped F-IDF values across the United States and
42 found that certain areas are more prone to flash floods than others. The amount of rain and the
43 size of the basin area are the most important factors in determining how severe a flash flood is.
44 This new quantification tool can help experts better identify and respond to flash flood risks.

45 **1 Introduction**

46 Flash floods, by definition, are a type of flood that occur within minutes to several hours
47 of heavy rainfall or other causes (Doswell III, 2015; Gourley et al., 2013; Hong et al., 2013). In

48 recent years, fatalities and damage caused by flash flooding have been increasing worldwide,
49 making it one of the most destructive weather types (Ashley & Ashley, 2008).

50 To identify flash flood risks, researchers have sought various approaches. One of the
51 most common practices for flash flood warning over the US and the world is the Flash Flood
52 Guidance (FFG) methodology (Georgakakos et al., 2022). It has been adopted as the operational
53 early-warning systems for flash flooding by the US National Weather Service since the 1970s
54 (Georgakakos, 1986). FFG is defined as an estimate of total rainfall that causes bankful flow. As
55 it suggests, this method does not take into account the full continuum of land surface responses to
56 extreme rainfall and river routing processes. Beyond FFG, there are other attempts to quantify
57 flash flood risks. We generalize them into event-dependent and event-independent approaches.
58 An event-dependent approach directly calculates flash flood risks based on archived flash flood
59 events (Alipour et al., 2020) or a flashiness index (Gannon et al., 2022; Li et al., 2022; Saharia et
60 al., 2017, 2021; Smith & Smith, 2015). The term flashiness index was introduced to measure
61 how quickly and how high streamflow rises in response to an event (Baker et al., 2004). Among
62 variants of flashiness index, the Richards-Baker Flashiness Index (RBI) is one of the earliest
63 indices, denoted by the time derivative of daily streamflow (Baker et al., 2004). Gannon et al.
64 (2022) evaluated the RBI at daily time scales and found little or no correspondence between
65 basin responses and watershed area. This result differs with Saharia et al. (2017) who revealed a
66 significant relationship of increasing flashiness with smaller watersheds, with the discrepancy
67 being attributed to the latter study's use of sub-hourly stream gage data instead of daily. Since it
68 is event-dependent, this approach presumably delivers accurate and precise results. However, it
69 is heavily based on a dense observational network. Alternatively, an event-independent approach
70 seeks a statistical model that relates climate variables and basin physiography to flash flood risk
71 (Lin et al., 2020; Ma et al., 2019). In doing so, this approach bypasses the requirement for
72 observations, which is particularly useful in ungauged basins or rural regions. Its validity,
73 however, requires particular attention.

74 Given the dense stream gage network in the US, we propose a new method using the
75 flashiness index applied to specific events. Although the definition of flashiness is diverse, this
76 study adopts the approach of estimating the slope of the rising limb of the hydrograph to reflect
77 the flood rising rate (Baker, 2004; Li et al., 2022; Saharia et al., 2017; Smith & Smith, 2015).

78 The flashiness index used in previous studies is only a static quantity that is irrespective of event
79 frequency and duration (Li et al., 2022; Saharia et al., 2017, 2021; Smith & Smith, 2015).
80 Weather forecasters, emergency responders, and the public are particularly concerned about the
81 degree of severity of a flash flood event, which needs to be quantified by frequency.
82 Additionally, we particularly value the representativeness of this index with respect to simplicity
83 and reproducibility. In light of these concerns, we adopt the idea from the Rainfall Intensity-
84 Duration-Frequency (R-IDF) curve that encapsulates three-dimensional information of a rainfall
85 event (Perica et al. 2013), and apply it to quantify a flash flood event. Hence, we introduce the
86 Flashiness-Intensity-Duration-Frequency (F-IDF) curve for the first time. Similar to the R-IDF
87 curve, the F-IDF curve describes the intensity (based on flashiness values), duration, and
88 frequency of flash flood events. We envision such a measure has practical implications in flash
89 flood forecasting and risk management. The aim of this article is threefold: (1) introducing the F-
90 IDF curve; (2) mapping F-IDF values for all US stream gages; and (3) investigating geographical
91 and hydrometeorological factors associated with F-IDF values. The newly introduced F-IDF
92 curve can be applied to observed or simulated hydrographs, meaning that it can be integrated
93 into any flood forecast system. We discuss how this new method can benefit hydrologic science,
94 hydrologic modelers, emergency responders, and city planners.

95 **2 Materials and Methods**

96 2.1 Flashiness-Intensity-Duration-Frequency

97 The F-IDF curves in this study are computed as follows: (1) Find the maximum rising
98 (positive) slope S of a hydrograph using a recursive moving time window (i.e., $D=1$ hour, 2
99 hours, 3 hours, 4 hours, 5 hours, and 6 hours) over the available period of streamflow record; (2)
100 Extract the annual maxima for each duration D ; (3) Fit the annual maxima into a general extreme
101 value distribution (GEV) and logPearson Type III distribution (LP3); (4) Find an optimal fit
102 based on the Bayesian Information Criterion; and (5) Return flashiness values for different
103 frequencies (i.e., 1-in-2-years, 1-in-5-years, 1-in-10-years, 1-in-25-years, 1-in-50-years, and 1-in-

104 100-years). The resulting flashiness value F is a measure of rapidness and magnitude changes
105 over the time window and is represented in Eq.1. An illustrative example is given in Fig. 1a.

106
$$F = \frac{\max \{O_t - O_{t-1}, O_t - O_{t-2}, \dots, O_t - O_{t-d}\}}{FAC \times d}, \quad (1)$$

107 where O_t is the observed streamflow time series at time t , d is the duration, FAC is the drainage
108 area (km^2). The unit of F is dependent on the observation but is generally expressed in units of
109 $[L/T^2]$. We standardize the unit of flashiness value to be measured in mm/h^2 . In this study, we
110 use the USGS stream gage record at a 15-minute time interval, so a conversion factor 0.4078 is
111 applied to convert $ft^3/s/km^2/15\text{-min}$ to mm/h^2 .

112 Repeating the process of calculating flashiness values at different durations and different
113 frequencies, we can depict the F-IDF curve as shown in Fig. 1b for one site. The shape of the F-
114 IDF curve is similar to the rainfall IDF curve, where intensity decreases with longer duration but
115 increases with event rarity.

116

117 Figure 1. (a) An illustrative example of calculating Flashiness-Intensity-Duration-Frequency
 118 values. The figure is produced with the Python Matplotlib library; (b) The empirical F-IDF plot
 119 and points are real events that surpass 2-year flashiness values.

120 There are several noteworthy points in calculating F-IDF values. First, because flash
 121 floods typically occur within 6 hours of the causative rainfall (Li et al., 2022), we did not
 122 consider events with durations greater than six hours. Second, we select two extreme value
 123 distributions in this study: (1) LP3 distribution and (2) GEV distribution. The LP3 distribution is
 124 a common approach in hydrologic frequency analysis, recommended by the US Water Resources
 125 Council (Singh, 1998). The GEV is an alternative approach that harmonizes the type I, type II,
 126 and type III extreme value distributions into a single family to allow a continuous range of
 127 possible shapes. Wallis & Wood (1985) compared two methods and found the goodness-of-fit
 128 for the two methods varied across different sites. Third, given the short gage record length (22.3

129 years), we only extrapolate return periods to 100 years; otherwise, there are large uncertainties
130 associated with the fitted GEV model (details refer to Section 3.1).

131 **3 Data**

132 3.1 CONUS-wide streamflow

133 We intended to collect 15-min streamflow time series data for all stream gages over the
134 CONUS from 1950 to 2020. However, not all gauge sites have such data length, especially for
135 sub-hourly instantaneous values. A map of stream gage data length distribution is shown in Fig.
136 S1. We filter out gages that have available data of less than 20 years to ensure enough data
137 samples for fitting the extreme value distributions. There are 3,722 gages left after filtering.
138 Next, we harmonize an equal time interval of 15 minutes for all stream gages by using linear
139 interpolation because some gages have an interval of 30 minutes. The linear interpolation method
140 is often used to fill in gaps in streamflow data (Pestrono et al., 2010). After preprocessing, those
141 data are analysis-ready to feed into the pipeline described in Section 2.1.

142 3.2 Catchment attributes

143 To analyze the flashiness values with basin characteristics, we use the basin attributes
144 from the HydroATLAS dataset (Linke et al., 2019). These attributes include eight sections:
145 Hydrology (i.e., annual runoff, precipitation, natural discharge, inundation extent, groundwater
146 table, river area, and river volume), Physiography (i.e., channel slope, catchment slope,
147 elevation, and drainage area), Climate (i.e., annual precipitation, potential evaporation, actual
148 evaporation, climate moisture index, aridity index, air temperature, snow cover), Soils &
149 Geology (i.e., soil water content, clay fraction, silt fraction, sand fraction, karst fraction, soil
150 erosion), Human (i.e., road density, urban density, population), Land Cover (i.e., area extent of
151 trees, shrubs, herbaceous, cultivated land, water bodies, snow, and artificial lands), Natural
152 Vegetation (i.e., evergreen, deciduous, savanna, grassland, tundra, desert), and Wetland (i.e.,
153 lake reservoir, river, and peatland). There are 59 basin attributes in total used in this study. We
154 spatially join these attributes to the catchments of all stream gages and use the values

155 representing the total watershed upstream of the gage. A detailed description of these attributes is
156 provided in Linke et al. (2019).

157 **4 Results**

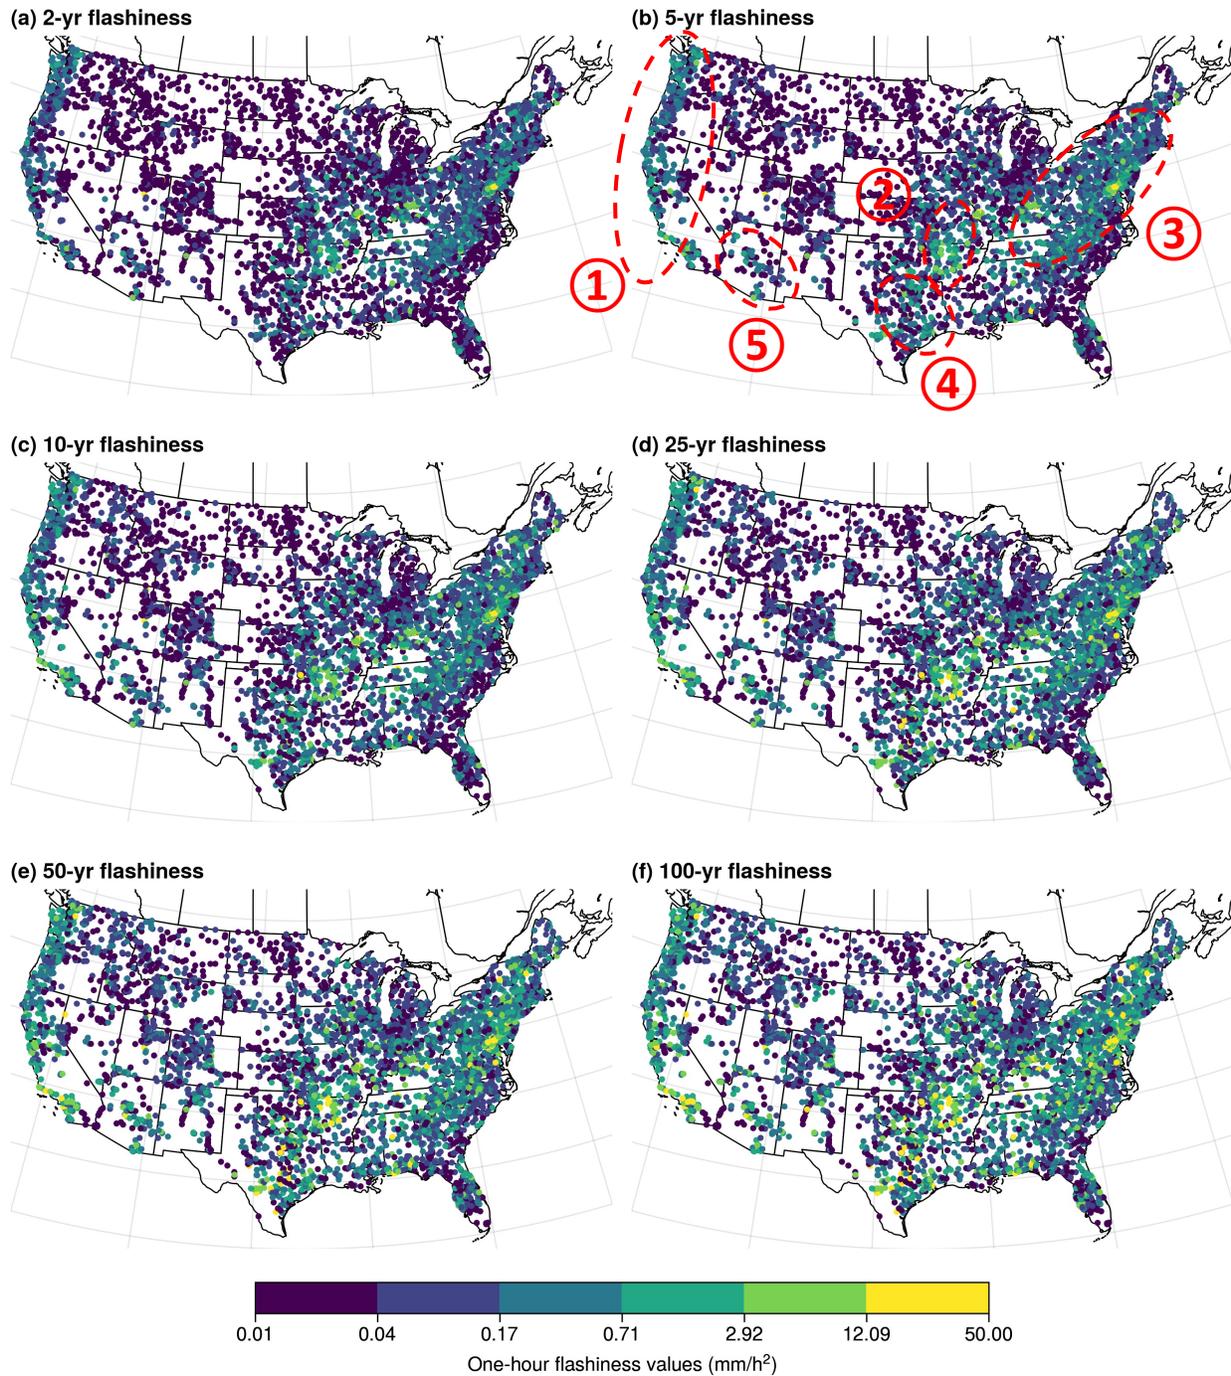

158 4.1 Mapping CONUS-wide F-IDF values

159 After iterating through steps 1-5 in Section 2.1 for each stream gage, we can map the
160 CONUS-wide F-IDF values. Figure 2 shows the one-hour flashiness values at six return periods
161 (2-year, 5-year, 10-year, 25-year, 50-year, and 100-year) as an example. Maps for other
162 durations (i.e., 2-hour, 3-hour, 4-hour, 5-hour, and 6-hour) can be found in Figs. S2-6 in the
163 Supplementary File. **A general observation for these maps as indicated in Fig. 1b is that F-**
164 **IDF values decrease with frequency and duration, in a similar manner as with R-IDF**
165 **values.** We can easily identify flashy regions in the CONUS by clustering stream gages that have
166 flashiness values larger than 1 (shown in Fig. 2b). Those five regions are (1) West Coast, (2)
167 Missouri Valley, (3) the Appalachians, (4) Flash Flood Alley, and (5) Southwest. The results
168 agree well with Saharia et al. (2017) and Li et al. (2022), despite slight differences in defining
169 the flashiness variable. We also compared our results with real flash flood events from 1970 to
170 2020 in a newly developed US flood database (Fig. S7; Li et al., 2021). These flash flood events
171 were verified by the US National Weather Service. Our identified regions also emerge, except
172 for the Pacific Northwest region, which has a low incidence of flash flood reports. A similar
173 finding is reached by Smith & Smith (2015), who reported the differences are in nature due to
174 different measures.

175 The main drivers for flash floods are region-dependent. On the West Coast, the main
176 atmospheric agent for flash flooding is atmospheric rivers, which transport considerable moisture
177 from the tropics to mid-latitudes. Even though atmospheric rivers produce long-duration winter
178 rainfall and snowfall, the steeply sloped terrain and compact watersheds can generate fast-rising
179 runoff (Saharia et al., 2017; Smith & Smith, 2015). Further inland, the contributions of warm-
180 season thunderstorms to flash flood occurrences start to dominate, especially for the Missouri
181 Valley (Region 2) and Flash Flood Alley region (Region 4). The destructive flash floods in 2022
182 in these two regions were the result of training thunderstorms that produced several record-
183 setting flood events. Flash Flood Alley also bears frequent tropical cyclones and hurricanes off

184 the Gulf Coast. The Appalachians (Region 3) are another known hot spot for flash flooding,
185 extending from Georgia up to Maine. Besides the hilly terrain, extratropical cyclones are the
186 synoptic weather types that frequently hit this region and result in a sequence of flood events (Li
187 et al., 2021). The Southwest (Region 5) is renowned for its hot and dry environment that initiates
188 convective thunderstorms during the North American monsoon season (Smith et al., 2019).
189 Besides the atmospheric forcings, land surface conditions such as impervious area ratio,
190 antecedent soil moisture, groundwater level, catchment drainage density, etc., jointly determine
191 flash flood severity.

192

193

194 Figure 2. Maps of F-IDF values at 1-hour duration. Highlighted (numbers from 1-5) regions are
 195 clustered flashy regions in the CONUS. 1: West Coast; 2: Missouri Valley; 3: the Appalachians;
 196 4: Flash Flood Alley; and 5: Southwest.

197

198 4.2 Factors determining flashiness values

199 We present a comprehensive view of factors determining flashiness values by utilizing 59
200 basin attributes and analyzing their correlation with flashiness. Figure 3 depicts the Spearman
201 Correlation Coefficient (CC) between flashiness values and 59 basin attributes across 3,722 gage
202 sites. For each site, we have CCs for six event durations and six return periods, but only the
203 minimum, median, and maximum values are taken in the table and grouped into Hydrology,
204 Physiography, Climate, Soils & Geology, Human, Land Cover, Natural Vegetation, and
205 Wetland. Overall, **climate** exerts the most positive correlation with flashiness values, with
206 annual precipitation ranked 1st place (Median CC=0.42), followed by actual evaporation and
207 moisture index (CCs=0.4), aridity index (CC=0.39), and air temperature (CC=0.28). It's worth
208 noting that the aridity index is positively related to the amount of moisture in the land. In other
209 words, the lower the aridity index, the drier the land is. **Hydrologic variables** are mostly
210 negatively correlated with flashiness in decreasing order: natural discharge (CC=-0.20), degree
211 of regulation (CC=-0.27), river volume (CC=-0.32), river area (CC=-0.35). The exception is land
212 surface runoff which has positive CC of 0.38. **Physiographic variables** exhibit a negative
213 correlation with flashiness, with elevation (CC=-0.28) and drainage area (CC=-0.43) being the
214 most significant factors. The **soils & geology** group has a relatively weak association with
215 flashiness. Soil water content has the greatest CC of 0.39 within this class, followed by clay
216 fraction (CC=0.19), silt fraction (CC=0.09), and sand fraction (CC=-0.16). The **human** group
217 shows positive correlations with road density (CC=0.32) and urban density (CC=0.23) being the
218 most significant ones. The notable features in the **land cover** group are deciduous trees
219 (CC=0.25), artificial surface (CC=0.16), herbaceous (CC=-0.25), and deciduous shrubs (CC=-
220 0.38). Similar to land cover, the **natural vegetation** group shows the temperate deciduous region
221 has a positive correlation (CC=0.24) with flashiness, while grassland (CC=-0.34), open shrub
222 (CC=-0.31), boreal evergreen (CC=-0.25), and boreal deciduous (CC=-0.23) have negative
223 correlations. The **wetland** group does not exhibit a significant positive correlation.

224 The controlling factors above can be summarized as follows. First, small river reaches
225 tend to have higher flashiness values, as the negative correlations between river area, volume,
226 and natural discharge testify this point. Second, flood defense infrastructures impede flash flood
227 generation, as indicated by the negative impact of the degree of regulation. Third, flashiness is

228 highly related to wetness or annual precipitation. Fourth, flash floods are typically not snowmelt-
 229 driven processes as seen with the weakly negative correlations to snow cover. Fifth, regarding
 230 soil types, the degrees of soil types contributing to flashiness are ranked as: clay>silt>sand,
 231 which is a reversed order of permeability. Sixth, wet soils, urban density, and road density help
 232 generate flash floods by impeding soil infiltration. Lastly, dense vegetation and land cover (e.g.,
 233 shrub and grassland) increase surface roughness and thus negatively correlate with flashiness.

234

235 Figure 3. A table of Spearman Correlation Coefficients between flashiness and 59 basin
 236 attributes. A single asterisk (*) indicate 95% confidence level, and two asterisks (**)
 237 indicate 99% confidence level to reject a null hypothesis (zero correlation).

238 A unique finding in this study is the correlation of flashiness to basin attributes changes
 239 with regard to flash flood frequency and duration. We divide the 59 factors into positive

240 correlation and negative correlation and plot their respective changes with regard to return
 241 periods and durations in Fig. 4. The significance of each slope is tested against a zero slope with
 242 the general linear F-statistics. As the occurrence of flash flood events becomes less frequent (i.e.,
 243 larger return period), the absolute correlation coefficient decreases. When reaching higher levels
 244 of intensity (i.e., 100-year event), the event flashiness is less influenced by basin attributes as the
 245 causative rainfall emerges as the primary driver. The correlation coefficients increase with the
 246 duration of the event (see Figs. 4b and 4d). Likewise, correlation increases with longer-duration
 247 events, as shown in the F-IDF curve in Fig.1b, and becomes more influenced by basin attributes.

248

249 Figure 4. Plots of positive and negative correlation coefficients (by aggregating respective
 250 variables) with respect to return periods and duration. The black dotted line shows the mean
 251 correlation coefficient while the band shows the interquartile range from Q25 to Q75. The
 252 significance of the slope is tested against a zero slope using the general linear F-statistic with the

253 fitted regression model (equation). A single asterisk (*) indicates 95% confidence level and two
254 asterisks (**) indicate 99% confidence level.

255 **5 Discussion**

256 5.1 The representativeness of flashiness index

257 In this study, we choose the maximum sub-hourly time derivative of streamflow over a
258 time window as the basis to build the F-IDF curves. First, using data collected at a time scale
259 appropriate for the application requires consideration. For investigations of flash flooding, the
260 time step needs to be sub-hourly. Acknowledging many other variants of flashiness indices
261 (Gannon et al., 2022; Kim & Choi, 2011; Saharia et al., 2017, 2021; Smith & Smith, 2015), this
262 approach has several benefits. First, it is fairly simple and reproducible. The most important
263 factors we consider the new index is the simplicity and reproducibility as it is easy to adopt and
264 comprehend by people. Second, it represents both the flood magnitude and flood rising limb
265 well, which is the nature of the term “flashiness” introduced by Baker et al. (2004). The first
266 point highlights the advantage of our method, compared to previous studies. For instance, Smith
267 & Smith (2015) fitted the discharge into a Generalized Pareto distribution (GPD), and use the
268 shape parameter to represent flashiness. This approach generally assumes a good fit of peak flow
269 with GPD, and it is not straightforward. Saharia et al. (2017, 2021) used a similar approach to
270 this study, but they rescaled the flashiness index into the range of 0-1 with an empirical
271 cumulative distribution function (ecdf). This approach prevents reproducibility since the number
272 of gages used in rescaling will affect the final results.

273 This study only considers flash flood events with durations less than six hours which is a
274 common definition for flash flooding (Clark et al., 2014). But for large basins (where the time of
275 concentration is long) or long-duration storm, this duration of F-IDF can be further extended to
276 12 and 24 hours by tuning the time window parameter in Eq.1.

277 5.2 Correlation with basin attributes

278 We calculated the Spearman Correlation Coefficient of flashiness index against 59 basin
279 attributes acquired from the HydroATLAS. As noted, the CC values are generally low ($CC < 0.6$)
280 for those factors. That is mainly because flash flooding, by nature, is a dynamic weather-driven
281 phenomenon that is challenging to predict by static features (such as basin slope and annual

282 precipitation). Similarly, Smith & Smith (2015) found that most of the CCs of number of flash
283 flood peaks with basin attributes are lower than 0.6. Second, the CC values are calculated with
284 uni-variate analysis, but we expect a higher value if we choose a multi-variate analysis, such as
285 regression models and/or machine learning models. Since the main focus of this study is to
286 provide a proof-of-concept of flashiness index, we will explore the predictability of a statistical
287 model in a future work.

288 5.3 Implications for hydrologic science and flash flood response

289 Our proposed new metrics – F-IDF curve, has implications not only for hydrologic
290 science but also for flash flood preparedness and responses. For the first time, this study
291 quantifies the frequency of flash floods based on the flashiness variable computed from observed
292 streamflow data, which provides a metric of the rapidity and severity of flooding. The same
293 variable and associated analysis can be applied to streamflow simulations from hydrologic
294 models. Then, the forecast flashiness and its associated frequency for a given duration can be
295 provided ahead of time. Weather forecasters can then use such metrics to guide the issuance of
296 flash flood warnings. Additionally, it is worth noting that the implementation of F-IDF curves is
297 model-agnostic, meaning that it can be integrated into any flood forecast system. In the U.S.,
298 such a system may include NOAA’s FLASH system, the National Water Model, etc. Second, for
299 hydrologic modelers, the F-IDF curve provides a means of identifying flash flood events. Prior to
300 this study, the identification of a flash flood event was vague and subjective. A common
301 definition – a flood that occurs within six hours of a rainfall event – was too obscure for
302 modelers to identify the start and end date of an event. However, with the help of the F-IDF
303 curve, one can easily establish a quantitative threshold to determine a flash flood event. For
304 instance, in a flood study, a two-year streamflow return period has often been used as a threshold
305 to identify a flood event, given that this threshold approximately corresponds to an overbank
306 flow rate (Li et al., 2022). Similarly, we can use a two-year flashiness value at a particular
307 duration to sift through flash flood events. Third, for city planners and decision-makers, the
308 existing F-IDF values can inform them of the risks of flash floods in the local area. Mitigation
309 strategies such as green infrastructure, low-impact development, and flood defenses can help
310 reduce flash flood risks. Fourth, assessing the risk of flash floods and planning accordingly is
311 crucial for emergency responders. In the US, it is common practice to block flooded roads to

312 prevent drivers from entering the water. However, this response requires proper guidance on
313 when and how quickly road barriers should be put in place. With the help of our F-IDF curves,
314 responders can access crucial information, such as the relationship between rate of action and the
315 flood rising rate. This information supports their decision-making processes, enabling them to
316 take timely actions that mitigate the risk associated with flash floods. There are undoubtedly
317 other applications beyond those mentioned here. In summary, this newly introduced metric has
318 implications not only for the scientific community but also for its potential role in the science-
319 informed, policy-making process.

320 **6 Conclusions**

321 This article introduces a new tool – the F-IDF curve – to quantify the intensity, duration,
322 and frequency of flash floods adopting a similar concept of the rainfall IDF curve. The F-IDF
323 curves are quantified for 3,722 US stream gages that have at least 20 years of observation of sub-
324 hourly streamflow. Additionally, the correlation of flashiness with regard to 59 basin attributes is
325 also explored and discussed. Lastly, the application of F-IDF curves is demonstrated to a recent,
326 devastating flash flood event – the 2021 Tennessee flooding. The conclusions are drawn as
327 follows:

- 328 1. F-IDF curves are capable of revealing the spatial variability of flashy basins across
329 the US and the following regions are identified as prone to flash flooding: the West
330 Coast, Missouri Valley, Appalachians, Flash Flood Alley in Texas, and the
331 Southwest.
- 332 2. Among the explored geographical and hydrometeorological factors, mean annual
333 precipitation is the most positively correlated with flashiness while the basin's
334 drainage area is the most negatively correlated variable.
- 335 3. The correlations weaken with increasing return periods and shorter event durations.
336 This is attributable to the extremity of the rainfall overwhelming the influence from
337 underlying basin attributes.

338 Similar to flood studies, predicting flashiness values in ungauged basins is a grand
339 challenge that warrants scientific exploration. We plan to integrate F-IDF curves into flash flood
340 forecast models over the US and beyond in a future work.
