Abstract

The mechanisms underlying decadal variability in Arctic sea ice remain an active area of research. Here we show that variability in boreal biomass burning (BB) emissions strongly influence simulated Arctic sea ice on multi-decadal timescales. In particular, we find that a strong acceleration in Arctic sea ice decline in the early 21st century in the Community Earth System Model version 2 (CESM2) is related to increased variability in prescribed CMIP6 BB emissions through summertime aerosol-cloud interactions. Furthermore, we find that the previously reported improvement in sea ice sensitivity to CO_2 emissions and global warming from CMIP5 to CMIP6 can be attributed in part to the imposed increased BB emission variability, at least in the CESM model. These results highlight the complexities of incorporating new observational data into model forcing, while also raising the question of a BB-forced contribution to the observed accelerated early 21st century Arctic sea ice loss.

Teaser

Increased inter-annual variability in CMIP6 prescribed biomass burning emissions in the early 21st century leads to enhanced simulated Arctic sea ice loss.

MAIN TEXT

Introduction

Arctic sea ice has experienced drastic reductions in extent, thickness and volume in recent decades, making it one of the most striking manifestations of anthropogenic climate change. Sea ice loss has been observed in all months of the year (*1*) but particularly notable is the loss of late-summer sea ice, with reductions in September ice extent and thickness since 1979 of roughly 45% and 66%, respectively (*1*, *2*). The September sea ice extent loss was largest in the early 21st century, reaching -13.3% per decade over the 14-year period of 1993–2006 (*3*). In contrast, the last 14

years have seen a slowdown of the rate of sea ice decline (*4*), with the 2007–2020 sea ice loss trend decreasing to -4.0% per decade (*3*).

The fact that internal climate variability can produce periods of up to two decades featuring enhanced or negligible sea ice loss even as global temperatures rise is well documented in the scientific literature (*5*, *6*, *7*, *8*). It is thus possible that the current period of reduced September sea ice trends is due solely to internal variability masking the anthropogenically-induced decline (*8*). For example, recent work suggests that the inter-decadal variability of Arctic atmospheric circulation related to teleconnections from the eastern-central tropical Pacific contributed to the abrupt warming and Arctic sea ice loss from 2007 to 2012 and the much slower decline in recent years (*4*). However, it is also possible that there is a previously unidentified forced contribution to the observed change in sea ice loss trends. For instance, a recent model-based analysis revealed that Arctic warming and sea ice loss in the second half of the 20^{th} century have been enhanced by emissions of ozone depleting substances (*9*). Other studies suggest that reductions in anthropogenic aerosols emissions between the 1980s and 2010 may have warmed the Arctic surface (*10*, *11*, *12*). Furthermore, the potential of biomass burning emissions from forest fires, which consist of mostly primary organic aerosols, black carbon, and reactive gases, to change the Arctic aerosol population and affect the rate of Arctic sea ice loss has also been brought forward (*13*, *14*), particularly in light of the severe wildfire seasons in recent years (*15*, *16*, *17*). In turn, a recent study shows that increasing large wildfires during autumn over the western United States are fueled by more fire-favorable weather associated with declines in Arctic sea ice during preceding months (*18*), emphasizing the complex interactions between fires and Arctic climate change.

Emissions from biomass burning (BB) prescribed for the sixth phase of the Climate Model Intercomparison Project (CMIP6) historical simulations (*19*) contain a period of strongly enhanced inter-annual variability between 1997–2014. Rather than reflecting an actual sudden increase in BB emission variability, the enhanced variability is due to a change in available observed BB emission data. In CMIP6, satellite-based emissions from the Global Fire Emissions Database (GFED) version 4 with small fires (*20*) from 1997 to 2014 were combined with either proxy records (when

available) or fire models to estimate historical BB emissions starting in 1750 (*19*). This large increase in variability starting in 1997 is new to the CMIP6 forcing and was not present in CMIP5 where decadal means were used to construct historical gridded BB emissions (*21*), such that the change in variability in the source datasets at the start of the GFED era did not affect the variability of prescribed emissions. Here we show that the increased inter-annual variability in prescribed CMIP6 historical BB emissions from wildfires starting in 1997 leads to an acceleration of simulated early 21st century Arctic sea ice loss in the CESM2 Large Ensemble (CESM2-LE) (*22*) due to non-linear aerosol-cloud interactions during the melt season. We identify this link by performing sensitivity experiments in which we remove the increased BB variability from the CMIP6 historical forcing while conserving the total integrated amount of BB emissions from 1997–2014. In order to isolate forced contributions to the Arctic sea ice evolution, we primarily focus on ensemble means, which reflect the model response to external forcing. We further show how this affects simulated sea ice sensitivities in the CESM, before discussing the implications of these model-based findings for the CMIP6 effort and the potential relevance for the observed evolution of Arctic sea ice.

Results

Accelerated sea ice loss in the CESM2-LE compared to the CESM1-LE

The evolution of Arctic sea ice area in September throughout the 20th and 21st centuries differs greatly between the CMIP5-forced version of the CESM, the CESM1-LE (*23*), and the CMIP6-forced version, the CESM2-LE (*22*) (Fig. 1A). Even before the start of the decline in Arctic sea ice in the later part of the 20th century, the two CESM versions have a large mean state difference, with the CESM1-LE simulating a thicker and more extensive sea ice cover compared to the CESM2-LE (*24*). In addition to this mean state difference, there is a statistically significant difference in the rate of Arctic sea ice loss starting in the mid-1990s (Fig. 1, B and C). The CESM1-LE September sea ice area anomaly and trend are gradually more negative with time until the Arctic reaches ice-free conditions every year (*25*). In contrast, the sea ice cover in the CESM2-LE experiences

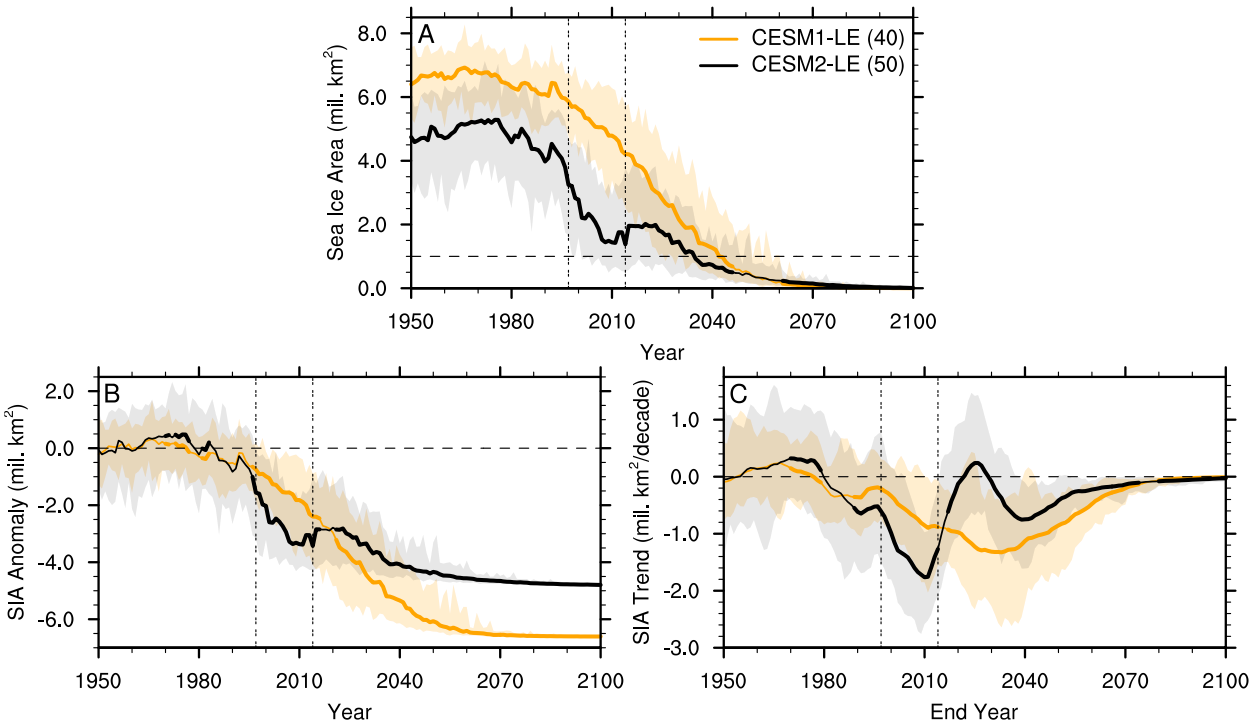

Fig. 1. Differences in the rate of Arctic sea ice loss. September (**A**) sea ice area (SIA), (**B**) SIA anomalies relative to the 1940–1969 average, and (**C**) 20-year linear SIA trends in the CESM1-LE and the CESM2-LE (the ensemble size is indicated in parentheses in the legend). The ensemble mean is shown by the solid line, the full ensemble range is shown by the shading, the horizontal dashed line indicates ice-free conditions in (A), no anomalies in (B) and no trend in (C), and the two vertical double-dashed lines indicate the GFED period. Years when the CESM1-LE and the CESM2-LE are statistically different at the 95% significance level are indicated with a thicker ensemble mean line and are determined using a two-sample Welch's t-test. In (C), values on the x-axis indicate the end year of the 20-year period over which the linear trend is computed.

a sharp decline in area starting in the mid-1990s up until the end of the first decade of the 21st century (Fig. 1B), with the ensemble mean sea ice loss trend reaching its highest value of about -1.8 million km^2/decade around end year 2010 (Fig. 1C). This is followed by a decade-long sea ice recovery in the CESM2-LE ensemble mean until $\sim$2025 characterized by neutral or even positive trends, after which the ensemble mean area anomaly and trend continue to become more negative until the sea ice cover melts out completely every summer (*24*). Note that this feature of the CESM2-LE sea ice evolution is present regardless of the choice of future CMIP6 emissions scenario (*24*), in all months of the year (Fig. S1; although it is most pronounced at the end of the summer), as well as in the version of the CESM2 that uses a high-top atmosphere model,

WACCM6, instead of the standard CESM2 atmosphere model, CAM6 (*24*).

Impact of BB emissions on simulated Arctic climate

We find that the change in prescribed BB emissions from CMIP5 to CMIP6 can explain much of the difference in Arctic sea ice evolution between the CESM1-LE and the CESM2-LE. Previous studies suggest that the aerosol forcing of CMIP5 simulations might have been too weak in recent decades (*26*, *27*). In CMIP6, BB emissions were updated to include inter-annual variability (*19*), rather than using decadal means (*21*) (Fig. 2). Although this decision allows for a more realistic depiction of BB emissions over the historical period, it also results in a sudden increase of the inter-annual variability in BB emissions in 1997 at the start of the GFED era (Fig. 2). This increase in variability is especially pronounced in the Northern Hemisphere (NH) mid-latitudes, where the variability increases by a factor of five compared to pre-GFED years (defined here as 1950–1996; Fig. 2A). The inter-annual variability in global BB emissions increases as well, although only by a factor of two (Fig. 2B).

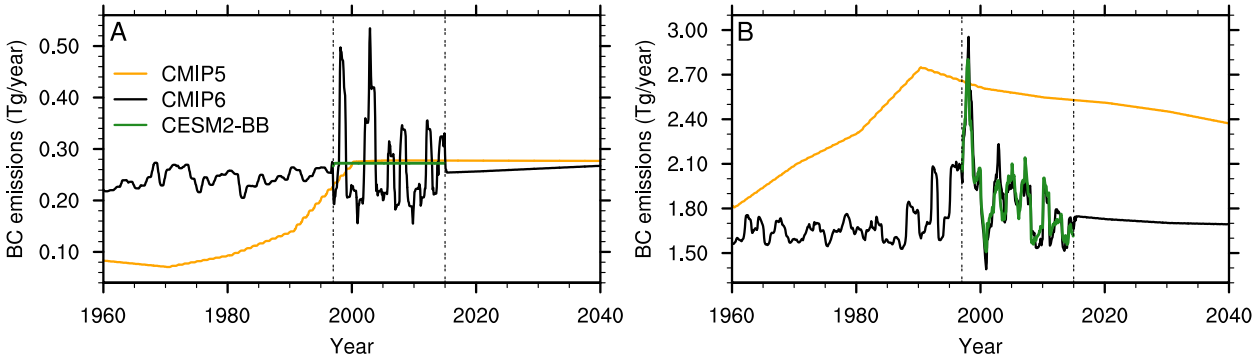

Fig. 2. Changes in BB forcing. Prescribed total black carbon emissions from BB (**A**) between 40–70°N and (**B**) globally in CMIP5, CMIP6 and the CESM2-BB, smoothed with a 12-month running mean. The two vertical double-dashed lines indicate the GFED period. Note that the range of values on the y-axis is different between the two panels, with higher values of total global black carbon emissions. Here we used black carbon emissions to represent BB emissions as it is the most radiatively important one, but all other prescribed BB emissions (dimethyl sulfide, primary organic matter, sulfur dioxide, sulfate aerosols and secondary organic aerosols) follow a similar time evolution as black carbon (not shown).

To isolate the impact of the increased BB variability over the GFED era on Arctic sea ice, we conducted sensitivity ensemble simulations (referred to as CESM2-BB hereafter) in which

the inter-annual variability in BB emissions from 1997–2014 between 40–70°N is removed but the integrated amount of emissions over that same period is retained (Fig. 2A; see Materials and Methods for details). As a result, the CESM2-BB has prescribed BB emissions over the NH mid-latitudes that are more similar to CMIP5 during the GFED period, with emissions pre- and post-GFED being the same as in CMIP6 (Fig. 2A). Because NH mid-latitude BB emissions make up only $\sim$14% of the global BB emissions, the variability of global BB emissions is practically unchanged in the CESM2-BB compared to CMIP6 (Fig. 2B).

The sensitivity experiments show that the warming of the Arctic (70–90°N) over the GFED period is more pronounced in the CESM2-LE compared to the CESM2-BB (Fig. 3A), with the largest difference over the central and Pacific sectors of the Arctic Ocean (Fig. S3, A and B). Specifically, the 20-year linear trends in Arctic surface air temperature in the CESM2-LE are significantly larger than the CESM2-BB over most of the GFED period (Fig. 3B), after which the trends reduce to neutral values in the ensemble mean until around end year 2025. In addition, the September Arctic sea ice area anomaly and trends are reduced (i.e., less negative) in the CESM2-BB compared to the CESM2-LE over the GFED period (Fig. 3, C and D). Similar results are found not just at the sea ice minimum but in all months of the year, although the difference between the CESM2-BB and the CESM2-LE is most pronounced from July to November (Fig. S1). This reduction in the rate of Arctic sea ice decline over the GFED era in the CESM2-BB is not limited to a specific region, but is present everywhere in the central Arctic Ocean and particularly over the Pacific sector of the Arctic (Fig. S3, C and D). As only the inter-annual variability in BB emissions over the GFED period differs between the two ensembles, these results allow us to conclude that the increased BB variability in CMIP6 over the GFED period is causing enhanced Arctic warming and sea ice decline since the late 1990s in the CESM2-LE. Note that the impact of the increased variability of BB emissions is not limited to the Arctic, but is also present north of 30°N, particularly over land, as shown in a companion paper that uses the same sensitivity simulations (*28*).

The impact of BB emissions on Arctic climate can be explained by aerosol-cloud interactions (Fig. 4). Freshly emitted BB particles are specified to be hydrophobic (primary carbon mode) in

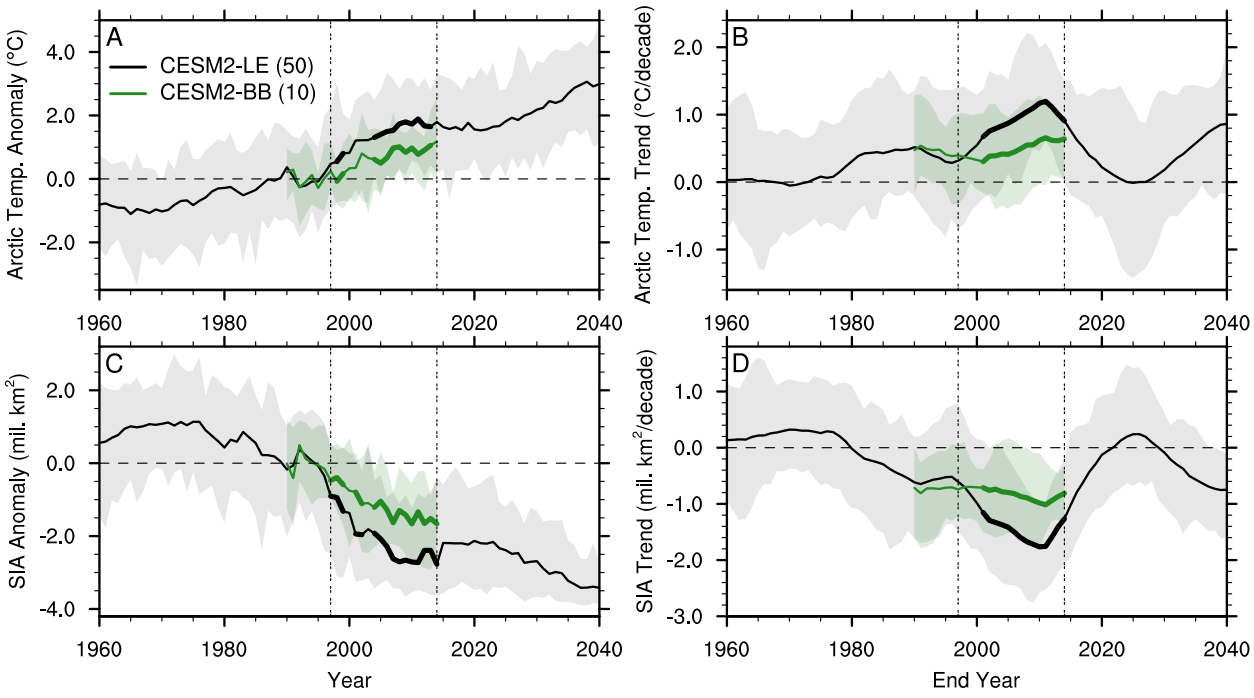

Fig. 3. BB emissions impact on Arctic climate. Annual Arctic (70–90°N) surface air temperature (**A**) anomalies relative to the 1990–1996 average (when the two simulations share the same forcing) and (**B**) 20-year linear trends, and September sea ice area (SIA) (**C**) anomalies relative to the 1990–1996 average and (**D**) 20-year linear trends in the CESM2-LE and the CESM2-BB (the ensemble size is indicated in parentheses in the legend). The ensemble mean is shown by the solid line, the full ensemble range is shown by the shading, the horizontal dashed line indicates no anomalies in (A and C) and no trend in (B and D), and the two vertical double-dashed lines indicate the GFED period. Years when the CESM2-LE and the CESM2-BB are statistically different at the 95% significance level are indicated with a thicker ensemble mean line and are determined using a two-sample Welch's t-test. Note that while the CESM2-BB has a smaller ensemble size than the CESM2-LE (10 versus 50 ensemble members), its ensemble size is sufficient to detect a forced sea ice response to the modified BB emissions (Fig. S2, C and D). In (B and D), values on the x-axis indicate the end year of the 20-year period over which the linear trend is computed.

the CESM model and as such cannot initially serve as cloud condensation nuclei (CCN). Through microphysical aging processes, these BB particles gradually become hydrophilic (*29*, *30*). We find that the inter-annual variability in BB emissions over the NH mid-latitudes in the CESM2-LE (Fig. 2A) is reflected in the Arctic summertime number concentration of aerosols in the primary carbon mode (Fig. S4), showing that fresh BB aerosols from those emissions are advected to the Arctic. However, the signature of the inter-annual variability in BB emissions is partly lost for the aged aerosols (i.e., those that can act as CCN; Fig. 4A). Specifically, years with smaller BB

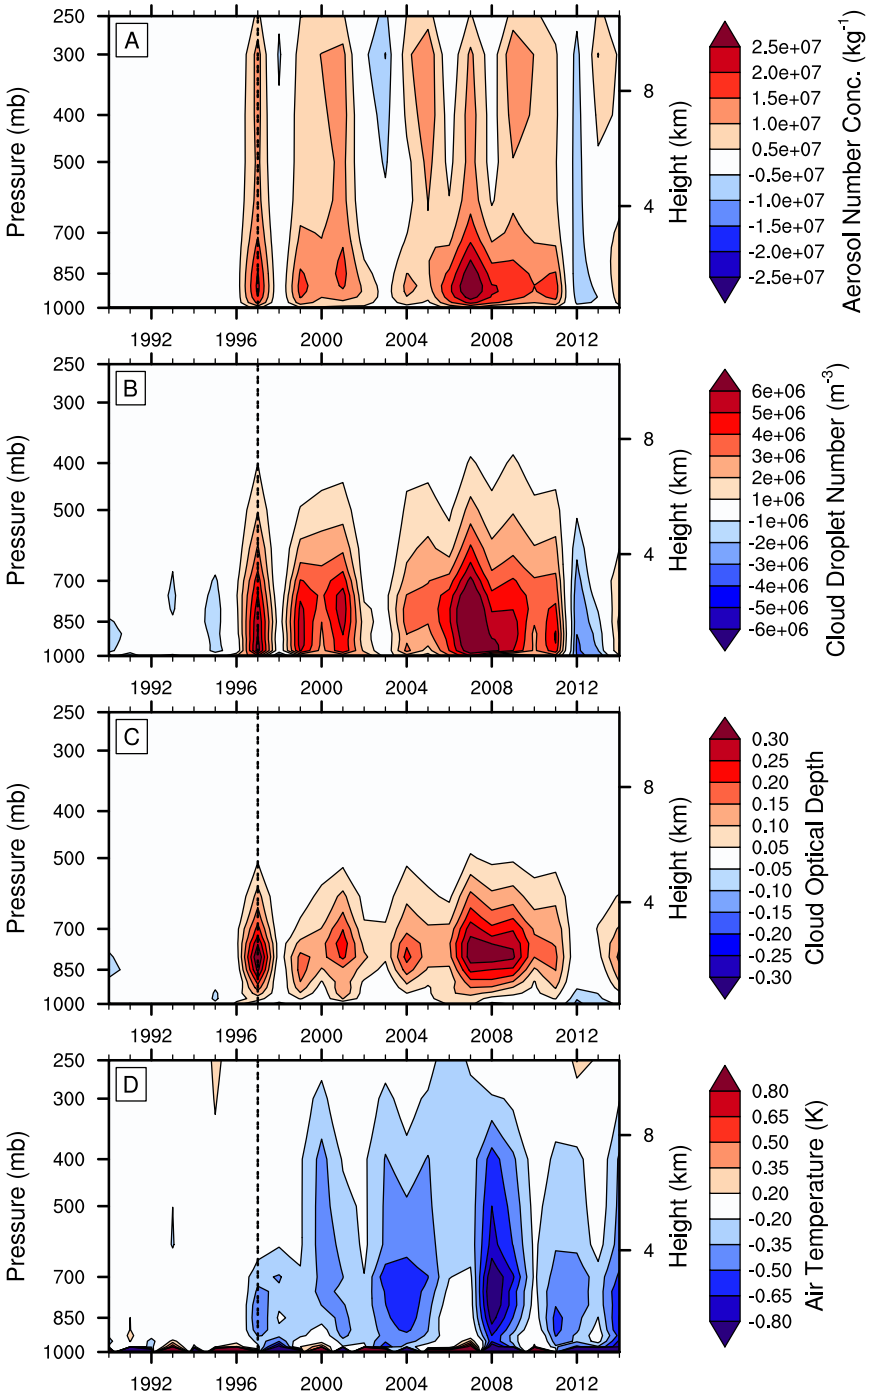

Fig. 4. BB emissions impact on Arctic aerosol-cloud interactions. Difference (CESM2-BB – CESM2-LE) in Arctic (70–90°N) summer (JJA) (**A**) number concentration of aerosols in the accumulation mode, (**B**) cloud condensation nuclei (CCN) concentration, (**C**) cloud optical depth and (**D**) air temperature with height. Positive differences (red) indicate larger values in the CESM2-BB and negative differences (blue) indicate larger values in the CESM2-LE. The vertical double-dashed line indicates the start of the GFED period.

emissions in the CESM2-LE compared to the CESM2-BB (i.e., 1997, 1999–2001, 2004–2011; see Fig. 2A) result in lower Arctic summertime number concentration of aerosols in the accumulation mode. Indeed, the larger aerosol emissions in the CESM2-BB during those years lead to larger aerosol numbers with smaller aerosol diameter (not shown) compared to the CESM2-LE (Fig. 4A). But the opposite is not true for years with larger BB emissions in the CESM2-LE than in the CESM2-BB (i.e., 1998, 2002–2003, 2012–2014; see Fig. 2A). During those years, there is very little difference between the two CESM simulations in terms of aerosol number concentration (Fig. 4A). This asymmetric response is likely a reflection of the observed non-linear and saturated response of CCN to aerosol loading (*31*, *32*). Indeed, it has been previously shown that cloud albedo has a non-linear response to aerosol emissions that diminishes with increasing emissions (*32*, see their Fig. 3). As a result of the larger concentration of summertime aerosols in the accumulation mode in the CESM2-BB in years with larger NH mid-latitude BB emissions, we find larger cloud droplet number concentration in the CESM2-BB compared to the CESM2-LE, especially close to the surface and up to about 500 mb (Fig. 4B). This results in higher lower-tropospheric cloud optical depth compared to the CESM2-LE over the GFED period (Fig. 4C) through indirect aerosol-cloud interactions, specifically the Twomey effect (*33*). The higher cloud optical depth is associated primarily with increases in cloud liquid amount (Fig. S5) and leads to a net cooling from the surface up to about 300 mb (Fig. 4D). Although the local impact of an increased aerosol loading in the Arctic is the non-linear result of competing cooling and warming aerosol indirect effects (*14*), the decrease in Arctic surface reflectivity during the melting season shifts the aerosol indirect effect towards cooling (*34*). Note that the temperature response towards the end of the GFED period is likely enhanced through snow/ice albedo feedback as the extent of the sea ice cover start to significantly differ between the two ensembles (Fig. 3C).

Impact of BB emissions on sea ice sensitivity

The observed loss of Arctic sea ice has been shown to be tightly coupled to increasing global mean surface air temperature (*35*, *36*, *37*) and cumulative anthropogenic CO_2 emissions (*38*). This metric

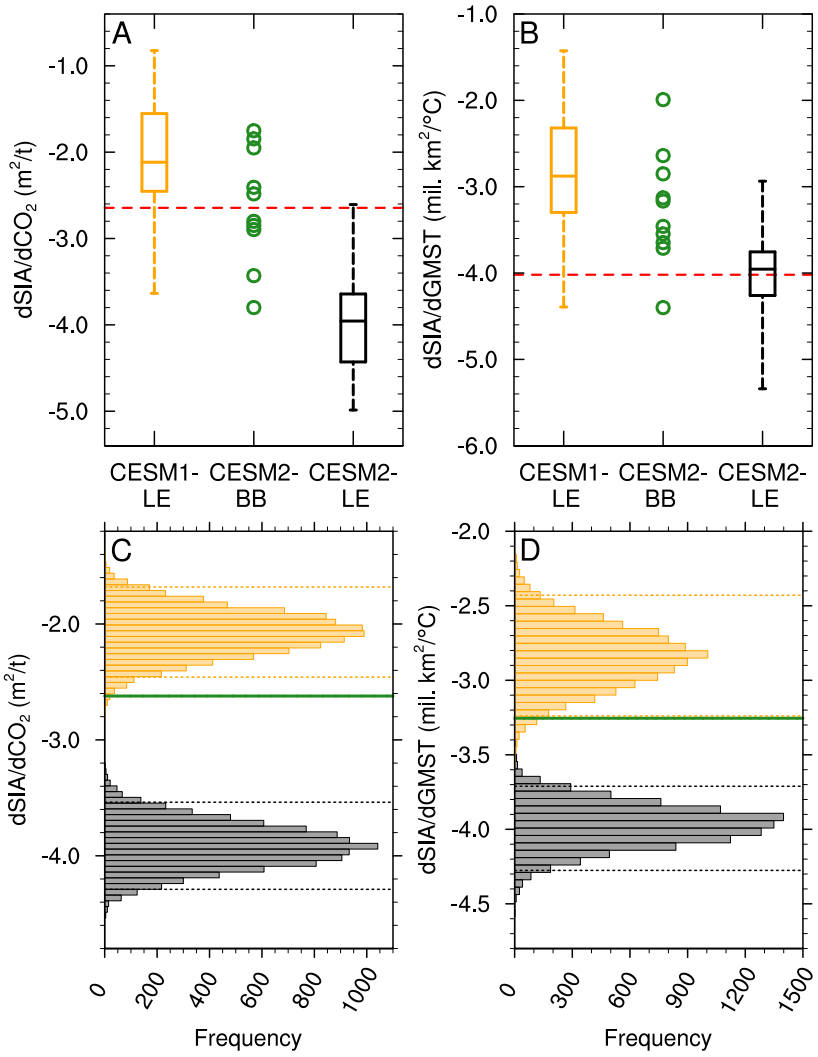

Fig. 5. BB emissions impact on sea ice sensitivity. Sea ice sensitivity to (**A**) cumulative anthropogenic CO_2 emissions (defined as the change in Arctic September sea ice area per change in cumulative anthropogenic CO_2 emissions in m^2 per tonne of CO_2) and (**B**) global annual mean surface temperature (defined as the change in Arctic September sea ice area per change in global mean surface temperature in million km^2 per °C) from 1979–2014 in the CESM1-LE, the CESM2-BB and the CESM2-LE, with the red dashed line showing the observed sensitivity. For the two large ensembles, the box shows the inter-quartile range, the line inside the box shows the median, and the whiskers show the minimum and maximum across all ensemble members, and for the CESM2-BB the green circles indicate the sea ice sensitivity of the 10 ensemble members. Histograms of sea ice sensitivity to (**C**) cumulative anthropogenic CO_2 emissions and (**D**) global annual mean surface air temperature obtained by bootstrapping the CESM1-LE and CESM2-LE ensemble means with 10 members 10,000 times, with the dotted lines showing the 95% confidence range for each distribution and the green line indicating the ensemble mean sensitivity of the CESM2-BB.

of sea ice sensitivity to CO_2 and global warming is commonly used by the sea ice community and has even been proposed as a way to reduce the uncertainty range of future sea ice evolution

(*38*, *39*). Previous literature has shown that models usually simulate a lower sensitivity of Arctic sea ice loss per degree of global warming than has been observed (*36*, *38*, *40*) and simulated Arctic sea ice retreat has been found to be accurate only in runs that have too much global warming, which suggests that models may be getting the right Arctic sea ice retreat for the wrong reasons (*40*). More recently, the CMIP6 multi-model ensemble mean was shown to provide a more realistic estimate of the sensitivity of September Arctic sea ice area to a given amount of anthropogenic CO_2 emissions and global warming compared with earlier CMIP experiments (*41*). It was, however, unclear whether this change reflects an improvement of model physics or primarily arises from differences in the historical forcing in CMIP6 relative to CMIP5, in particular differences in BB emissions and ozone (*41*).

In agreement with what was reported for CMIP6 models as a group (*41*), we find that the sea ice sensitivity to cumulative anthropogenic CO_2 emissions and global mean surface temperature is generally higher in the CMIP6-forced version of the CESM, the CESM2-LE, compared to the CMIP5-forced version, the CESM1-LE (Fig. 5, A and B). In contrast, the sea ice sensitivities of the CESM2-BB falls somewhere in between the range of sea ice sensitivities of the CESM1-LE and the CESM2-LE, although all 10 ensemble members of the CESM2-BB overlap with at least one of the large ensemble distributions if not both. Note that trends in September sea ice area and global mean surface temperature are related in these simulations, with more sea ice loss present in simulations with more global warming. As such, the change in sea ice sensitivity to global mean surface temperature in the CESM2-BB is influenced by both factors. Using bootstrapping, we show that the sea ice sensitivity of the CESM2-BB ensemble is statistically distinct from the CESM1-LE and the CESM2-LE at the 95% confidence level when accounting for the different ensemble size of the three CESM simulations (Fig. 5, C and D). Note that bootstrapping, or randomly resampling with replacement to generate statistics, requires no distribution assumptions and is only possible with sufficiently large ensembles. Hence, based on results from the CESM model, the increased variability in BB emissions from CMIP5 to CMIP6 seems to be responsible in part for the increased sea ice sensitivity to CO_2 and global warming recently reported by the SIMIP Community (*41*),

with the rest related to other changes in historical forcing and/or improvement of model physics. This is especially true for the sea ice sensitivity to CO_2, as temperature is also affected by the change in BB emissions but CO_2 concentrations are typically prescribed in CMIP6 simulations.

Discussion

We showed that a large part of the enhanced early 21st century Arctic surface warming and September sea ice decline in the CESM2-LE compared to the CESM1-LE can be attributed to the increased inter-annual variability in prescribed NH mid-latitude BB emissions during the GFED period in the CMIP6 forcing. Specifically, we showed that the increased BB variability enhances warming due to non-linear aerosol-cloud interactions, as decreased cloud optical depth during years with low BB-related aerosol burdens enhances warming more than years with high BB-related aerosol burdens lead to cooling. Hence, the increased BB variability over the GFED period leads to an additional forced sea ice loss in the CESM2-LE beyond the one driven by increases in greenhouse gases (*42*) and internal variability (*6*, *43*, *44*).

The presence of this non-greenhouse gas forced sea ice loss in the early 21st century in models also affects the sea ice sensitivity, a metric often used to evaluate model performance (*25*, *37*, *38*, *41*). Specifically, we find that the increased inter-annual variability in BB emissions during the GFED era explains part of the increase in sea ice sensitivity to CO_2 emissions and global warming from the CMIP5-forced to the CMIP6-forced versions of the CESM. This is the second time that aerosol-related forcing changes have been shown to impact Arctic sea ice trends between CMIP generations (*45*), highlighting how sensitive sea ice is to the effects of aerosol emissions.

Interestingly, it is not only the CESM2 that shows an increase of the rate of Arctic sea ice decline over the GFED period, but some other CMIP6 models do as well (Figs. S6 and S7). From the 12 additional CMIP6 models assessed here (see Materials and Methods), four (ACCESS-ESM1.5, FGOALS-g3, MIROC6 and MPI-ESM1.2-HR) show an accelerated ensemble mean sea ice loss over the GFED period, although none of them as large as the CESM2. This indicates that the impact of BB emissions is likely not just limited to the CESM2 but may affect other CMIP6 models,

in agreement with results from a companion paper that finds increased surface downwelling shortwave radiation during the GFED period in several CMIP6 models in addition to the CESM2 (*28*). The fact that some CMIP6 models show a similar sea ice loss acceleration as the one attributed to the new BB emissions in the CESM2 while others do not calls for a better understanding of inter-model differences in light of their sensitivity to aerosol emissions. Furthermore, the sensitivity of the CESM2 to changes in BB variability raises the question as to whether the lack of inter-annual variability in aerosol forcing in the pre-industrial control and future scenario runs could be problematic.

Overall, our analysis shows that BB emissions can influence multi-decadal variations in Arctic sea ice. This work also demonstrates that changes in the variability of emissions, not just changes in the mean, can have large effects on climate through non-linear cloud feedbacks. As such, our findings suggest that the way short-lived climate forcings like BB emissions are prescribed in models can have unexpected remote effects in vulnerable regions such as the Arctic. This highlights the challenges associated with incorporating newly available observations into climate forcing datasets and the importance of avoiding temporal discontinuities, which may help guide decisions in future phases of CMIP. To avoid a sharp increase in BB variability in 1997 while still making use of the new satellite-based observations over the GFED period, we recommend re-assessing the variability of emissions pre-GFED, potentially through the use of an interactive fire model.

Finally, the early GFED period stands out as particularly variable in BB emissions north of 40°N, both in the real world and in the CMIP6 forcing (*19*). As discussed earlier, several studies have documented a steepening of the observed trend of Arctic sea ice decline since the mid-1990s (*46*, *47*) and a smaller trend since 2007 (*3*, *8*). This qualitatively matches the behavior simulated by almost all 50 ensemble members of the CESM2-LE (Fig. 6C) and some other CMIP6 models (Fig. S7). In contrast, only a few ensemble members of the CESM2-BB simulate a similar increase in negative sea ice area trend over the GFED period as seen in the observations, with no clear coherent response across the full ensemble (Fig. 6D). This raises the question of a potential role of BB emissions in the observed Arctic sea ice loss since the late 1990s. Notably, this is challenging

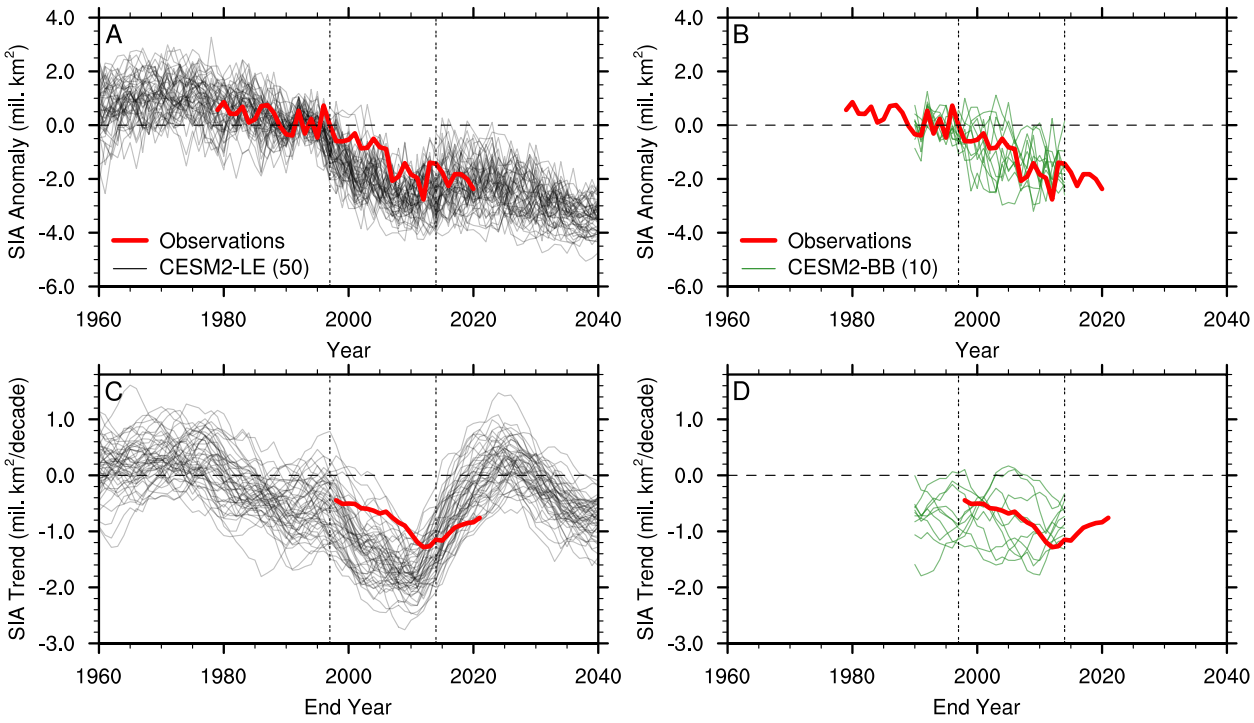

Fig. 6. Potential impact of BB emissions on observed Arctic sea ice decline. September sea ice area (SIA) (**A and B**) anomalies relative to the 1990–1996 average (when the two simulations share the same forcing) and (**C and D**) 20-year linear trends in each individual ensemble member of the (A and C) CESM2-LE and the (B and D) CESM2-BB (the ensemble size is indicated in parentheses in the legend) compared to observations. The horizontal dashed line indicates no anomalies in (A and B) and no trend in (C and D), and the two vertical double-dashed lines indicate the GFED period. In (C and D), values on the x-axis indicate the end year of the 20-year period over which the linear trend is computed.

to diagnose given the limitations of pre-GFED BB emission observations and the significant role of internal variability on Arctic sea ice trends (*6*, *7*, *8*, *44*). Indeed, when taking into account internal variability by comparing the observations to all individual ensemble members, we cannot say that the observed Arctic sea ice decline since the late 1990s is different from the CESM2-LE or the CESM2-BB (Fig. 6, A and B). However, our results using the CESM2 indicate that BB emission variability strongly influences simulated multi-decadal Arctic sea ice trends. This should be further investigated in light of the observed record and is especially timely given the record Arctic fire years in 2019 and 2020 (*15*, *16*, *17*), the recent observed positive trend in burned area and severity of NH wildfires (*48*, *49*, *50*), and the projected increase in wildfires in the future (*51*, *52*, *53*).

Materials and Methods

Observational data

Observed estimates of NH monthly sea ice area since the beginning of the continuous satellite record in 1979 are from the National Snow and Ice Data Center (NSIDC) Sea Ice Index version 3 (*54*), with the observational pole hole filled assuming sea ice concentration of 100%. Historical anthropogenic CO_2 emissions are taken from the historical budget of the Global Carbon Project (*55*). For global mean surface temperature, we use estimates from GISTemp v4 (*56*, *57*) and calculate anomalies relative to the period 1850–1900.

CESM simulations

The CESM Large Ensemble (CESM1-LE) (*23*) is a 40-member ensemble of the CESM1.1 model (*58*) that has been widely used for Arctic sea ice studies and generally performs well when compared to observations (*43*, *59*, *60*, *61*, *62*, *63*). Historical simulations span 1920 to 2005, while the RCP8.5 scenario simulations cover 2006 to 2100. The CESM1-LE uses the Community Atmosphere Model version 5 (CAM5) (*58*) along with a 3-mode version of the Modal Aerosol Module (MAM3) (*64*), and cloud-aerosol interactions are represented by the MG1 cloud microphysics scheme (*65*).

With several science and infrastructure improvements, the CESM2 model (*66*) is the latest generation of the CESM and NCAR's contribution to CMIP6. Specifically, aerosols are simulated through the use of the MAM4 approach (*67*) and cloud-aerosol interactions are represented by the updated Morrison and Gettelman scheme (MG2) (*68*). The CAM5 shallow convection, planetary boundary layer and cloud macrophysics schemes are replaced in CESM2 with an unified turbulence scheme, the Cloud Layers Unified By Binormals (CLUBB) (*69*). As a result of these improvements, the CESM2 shows large reductions in low-latitude precipitation and short-wave cloud radiative forcing biases, leading to improved historical simulations with respect to available observations compared to its previous major release, the CESM1.1 used in the CESM1-LE (*66*). Two

separate CESM2 configurations have been contributed to the CMIP6 effort, differing only in their atmosphere component: the "low-top" (40 km, with limited chemistry) Community Atmosphere Model version 6 (CAM6; referred to as CESM2) (*66*) and the "high-top" (140 km, with interactive chemistry) Whole Atmosphere Community Climate Model version 6 (WACCM6; referred to as CESM2-WACCM) (*70*). Previous analysis has shown that the low-top CESM2 simulates a thinner 20$^{\text{th}}$ century sea ice cover than the high-top CESM2-WACCM (*71*) and the CESM1-LE (*24*). Most of the analysis presented here focuses on a recently released large initial-condition ensemble (referred to as CESM2-LE) that uses the version of the CESM2 with CAM6 as the atmosphere component (*22*), but results from the CESM2-WACCM are also included in the comparison with other CMIP6 models (Figs. S6 and S7).

The CESM2-LE (*22*) is a 100-member large ensemble suite that was run from 1850 to 2014 under historical forcing and from 2015 to 2100 following the medium-to-high SSP3-7.0 scenario (*72*). The CESM2-LE initialization procedure was designed to include a mix of macro- and micro-perturbations, where macro-perturbations were initialized from 20 independent restart files at 10-year intervals (total of 20 ensemble members) and micro-initializations involved a small random perturbation in 20 members for 4 different start years of the pre-industrial control simulation meant to represent different AMOC states (total of 80 ensemble members). Note that most of this study focuses on the first 50 members of the CESM2-LE since those follow CMIP6 protocols in terms of BB emissions (*19*). For the second set of 50 members, the CMIP6 global BB emissions of all relevant species were smoothed in time from 1990–2020 to remove inter-annual variability based on the climate impacts of the high BB variability over the GFED period, as presented in this paper and a companion paper (*28*).

CESM2 sensitivity experiments with homogenized forcing

To investigate the impact of the increased inter-annual variability in BB emissions over the GFED period, we ran a set of sensitivity experiments using the CESM2 (referred to as CESM2-BB) in which we averaged BB emissions from 1997–2014, computed on a monthly basis, such that BB

emissions have a fixed annual cycle while keeping the same integrated amount of emissions over that same period. This approach is identical in nature to what was used in CMIP5 (*21*) and removes any sharp transition with BB emissions over pre-GFED years as well as with the SSP BB emissions since those are homogenized to the averaged GFED emissions. The CESM2-BB simulations are initialized in 1990 from the first 10 members of the CESM2 and only BB emissions over the 40–70°N latitudinal band from 1997–2014 are modified. This region is chosen to target BB emissions from NH mid-latitude wildfires, but similar results are found by removing the variability in BB emissions globally instead of only between 40–70°N (not shown), which highlights the impact of NH mid-latitudes fires on Arctic climate. These sensitivity simulations are the same as the first 10 members used in a companion paper (*28*).

Although the ensemble size of the CESM2-BB is much smaller compared to the CESM2-LE, we find that 10 ensemble members are enough to detect a forced response to the homogenized BB emissions in the CESM2. Specifically, we compare the first 50 members of the CESM2-LE to the last 50 members (Fig. S2, A and B), which also use homogenized BB emissions to avoid the increase in BB variability over the GFED era (*22*). With 10 ensemble members, we are able to detect a forced response that is statistically different in 2001 and from 2007–2011 for the September sea ice area and from 2009–2011 and 2025–2027 for the 20-year linear trend in September sea ice area (Fig. S2, C and D). Note, however, that for the last 50 members of the CESM2-LE the chosen smoothing technique and years over which the smoothing is applied differ from what we used in the CESM2-BB experiment. In particular, the smoothing in the CESM2-LE is applied globally over 1990–2020 using an 11-year running mean filter, such that the integrated amount of emissions over the GFED period is not the same as in the CMIP6 forcing (or the CESM2-BB). Nonetheless, the Arctic sea ice response to homogenized BB forcing is similar between the last 50 members of the CESM2-LE and the CESM2-BB.

CMIP6 simulations

We also use simulations from a subset of CMIP6 models that provided at least three ensemble members for the historical and SSP3-7.0 scenario simulations. As of December 2nd 2020, the models that met this criteria (excluding the CESM2 and CESM2-WACCM described above) are: ACCESS-CM2 (*73*, *74*), ACCESS-ESM1.5 (*75*, *76*), BCC-ESM1 (*77*, *78*), CanESM5 (*79*, *80*), EC-Earth3-Veg (*81*, *82*), FGOALS-g3 (*83*, *84*), IPSL-CM6A-LR (*85*, *86*), MIROC6 (*87*, *88*), MPI-ESM1.2-HR (*89*, *90*), MPI-ESM1.2-LR (*91*, *92*), MRI-ESM2.0 (*93*, *94*) and NorESM2-LM (*95*, *96*). In cases where the ScenarioMIP SSP3-7.0 simulation was not available, we then used the AerChemMIP SSP3-7.0 simulation that uses the same forcing as the ScenarioMIP SSP3-7.0 but only extends to the end of 2055 (*97*). Even if a modeling center provided more than three ensemble members, only the first three are used to allow for a consistent comparison across all CMIP6 models. Although using only CMIP6 models that provide at least three ensemble members limits the total number of CMIP6 models included in our analysis, it is necessary to choose an ensemble size that is large enough to represent the forced sea ice response to BB emissions, as some individual members of the CESM2-LE show different trajectories despite the identified forced response to the BB forcing (Fig. 6A). Using an ensemble size of three members was chosen as a compromise since the ensemble mean of the first three ensemble members of the CESM2-LE match the full ensemble mean reasonably well while requiring more members would further reduce the number of available CMIP6 models.

Criteria for determining sensitive versus not sensitive CMIP6 models

The CMIP6 models are separated into a sensitive and a not sensitive category based on whether they exhibit a similar sensitivity to the increased variability in BB emissions as the CESM2 (Figs. S6 and S7). First, we calculate 20-year linear trends in September sea ice area for each model, and compare the slope of the 20-year linear trends between the reference period of end years 1978–1990 and the acceleration period of end years 1997–2009. Note that we chose the last year of the acceleration period to be 2009 instead of the last year of the GFED era (i.e., 2014) based on when

the CESM2-LE and CESM2-WACCM reach their maximum negative September sea ice area trend (see Fig. S7). For a model to be characterized as sensitive, the slope of sea ice area trends over the acceleration period needs to be at least 2 times larger (in absolute value) than the slope of sea ice area trends over the reference period. This criteria is defined based on the relative increase in sea ice trend for each model to account for the different magnitudes of sea ice loss across all CMIP6 models (Fig. S7). We decided to choose two periods of same length and to exclude the years 1991–1996 from the reference period because of the Mount Pinatubo volcanic eruption in 1991 and the global cooling that followed for a few years, which resulted in a peak increase in Arctic sea ice extent about a year and a half after the eruption in some models (*98*). Note that the classification into the sensitive and not sensitive category is not affected by the choice of reference period or the exact magnitude of the accelerated sea ice loss.

Acknowledgments

Funding: P. DeRepentigny is supported by the Natural Sciences and Engineering Council of Canada (NSERC) and the Fonds de recherche du Québec – Nature et Technologies (FRQNT) through PhD scholarships and by NSF-OPP CAREER award 1847398. Part of the revisions of this manuscript were carried out while P. DeRepentigny was supported by NSF-AGS CAREER award 1554659 and the Advanced Study Program of the National Center for Atmospheric Research (NCAR). A. Jahn's and A. Barrett's contribution is supported by NSF-OPP CAREER award 1847398. Contributions from M. M. Holland, J.-F. Lamarque, C. Hannay, M. J. Mills, D. A. Bailey and S. Tilmes are supported by NCAR, which is a major facility sponsored by the NSF under Cooperative Agreement No. 1852977. J. E. Kay was supported by NSF-AGS CAREER award 1554659. The efforts of J. Fasullo were supported by NASA Award 80NSSC17K0565, by NSF Award #AGS-1419571, and by the Regional and Global Model Analysis (RGMA) component of the Earth and Environmental System Modeling Program of the U.S. Department of Energy's Office of Biological & Environmental Research (BER) via National Science Foundation IA 1844590.

The CESM project is supported primarily by the National Science Foundation (NSF). This material is based upon work supported by NCAR, which is a major facility sponsored by the NSF under Cooperative Agreement No. 1852977. Computing and data storage resources, including the Yellowstone (`http://n2t.net/ark:/85065/d7wd3xhc`) and Cheyenne (doi:10.5065/D6RX99HX) supercomputers, were provided by the Computational and Information Systems Laboratory (CISL) at NCAR. We thank all the scientists, software engineers, and administrators who contributed to the development of CESM and the CESM1 and CESM2 Large Ensemble Community Projects. We also acknowledge supercomputing resources provided by the IBS Center for Climate Physics

in South Korea for the CESM2 Large Ensemble Project.

We acknowledge the World Climate Research Programme, which, through its Working Group on Coupled Modelling, coordinated and promoted CMIP6. We thank the climate modeling groups for producing and making available their model output, the Earth System Grid Federation (ESGF) for archiving the data and providing access, and the multiple funding agencies who support CMIP6 and ESGF.

We also thank Alice DuVivier, Clara Deser, Walt N. Meier, Andrew Gettelman and Christina S. McCluskey for useful discussions and three anonymous reviewers for valuable comments on an earlier version of this manuscript. Data analysis and visualization were done using the NCAR Command Language (`http://dx.doi.org/10.5065/D6WD3XH5`).

Author contributions: P. DeRepentigny and A. Jahn designed the study. P. DeRepentigny performed the analysis and wrote the manuscript under the supervision of A. Jahn. M. M. Holland, J. Fasullo and J.-F. Lamarque contributed to the experiment design and provided CESM specific expertise. J. E. Kay provided valuable guidance on statistical analysis and cloud-aerosol-radiation interactions. C. Hannay and P. DeRepentigny conducted the sensitivity simulations. M. J. Mills and S. Tilmes provided aerosol emission expertise. D. A. Bailey provided valuable assistance for conducting the sensitivity simulations. A. Barrett compiled CMIP6 data. All authors provided critical feedback and collaborated in shaping the research, analysis and final version of the manuscript.

Competing interests: The authors declare no competing interests.

Data and materials availability: Previous and current versions of the CESM are freely available at `https://www.cesm.ucar.edu/models/`. The CESM2-LE data analyzed in this study can be accessed at `https://www.cesm.ucar.edu/projects/community-projects/LENS2/data-sets.html`. The CESM1-LE data can be found at `https://www.cesm.ucar.edu/projects/community-projects/LENS/`. Data from the CMIP6 models analyzed in this study are freely

available from the Earth System Grid Federation (ESGF) at `esgf-node.llnl.gov/search/cmip6/`. The CESM2-BB sensitivity simulations are available on NCAR's Geoscience Data Exchange (GDEX) at `https://gdex.ucar.edu/dataset/239_fasullo.html` (doi:10.5065/7f7c-zw94).

Supplementary Materials

Enhanced simulated early 21st century Arctic sea ice loss due to CMIP6 biomass burning emissions

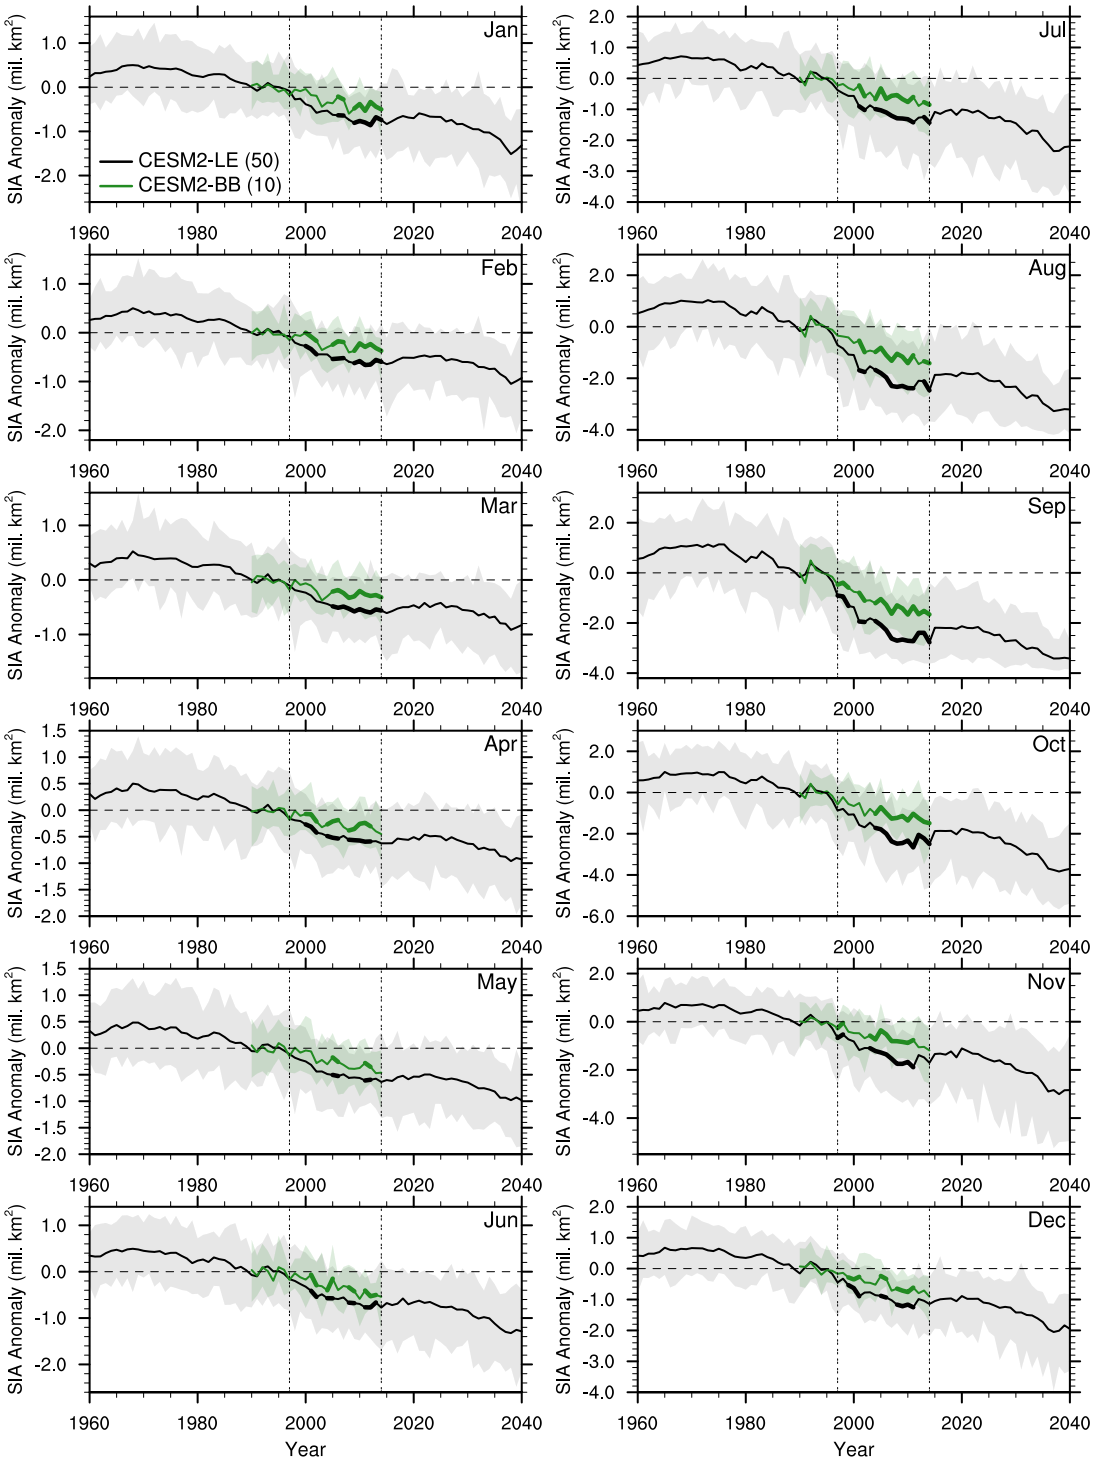

Fig. S1. BB emissions impact on Arctic sea ice in all months. Sea ice area (SIA) anomalies relative to the 1990–1996 average (when the two simulations share the same forcing) in each month of the year in the CESM2-LE and the CESM2-BB. The ensemble mean is shown by the solid line, the full ensemble range is shown by the shading, the horizontal dashed line indicates no anomalies, and the two vertical double-dashed lines indicate the GFED period. Years when the CESM2-LE and the CESM2-BB are statistically different at the 95% significance level are indicated with a thicker ensemble mean line and are determined using a two-sample Welch's t-test. Note that the range of values on the y-axis varies across all panels.

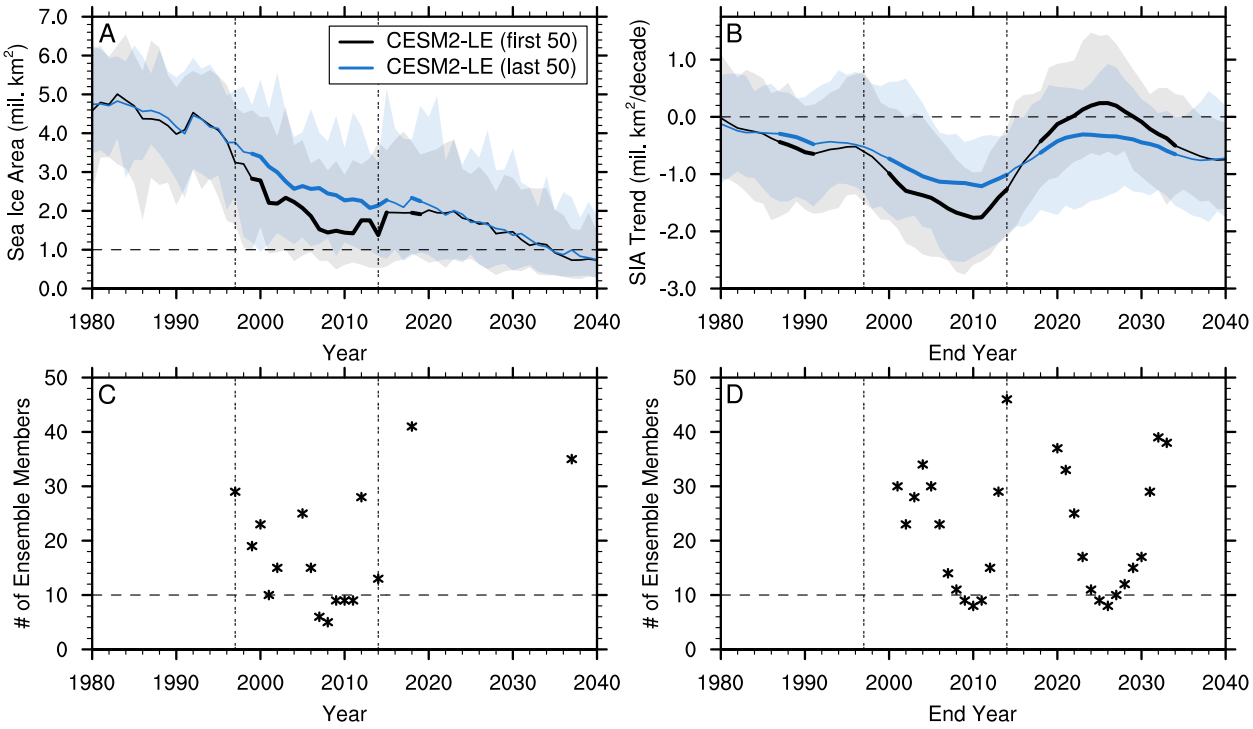

Fig. S2. Minimum number of ensemble members needed to detect a forced response to the homogenized BB emissions. September sea ice area (SIA) (**A**) anomalies relative to the 1940–1969 average and (**B**) 20-year linear trends in the first and last 50 members of the CESM2-LE. The ensemble mean is shown by the solid line and the full ensemble range is shown by the shading. Years when the first 50 and last 50 ensembles are statistically different at the 95% significance level are indicated with a thicker ensemble mean line and are determined using a two-sample Welch's t-test. Minimum number of ensemble members needed for the September SIA (**C**) anomalies relative to the 1940–1969 average and (**D**) 20-year linear trends between the first 50 and last 50 ensembles to be statistically different at the 95% significance level. This is done by bootstrapping the two ensembles 10,000 times with a sub-sample size varying from 2 to 50. The horizontal dashed line indicates no anomalies in (A), no trend in (A), and 10 ensemble members in (C and D), and the two vertical double-dashed lines indicate the GFED period. In (B and D), values on the x-axis indicate the end year of the 20-year period over which the linear trend is computed.

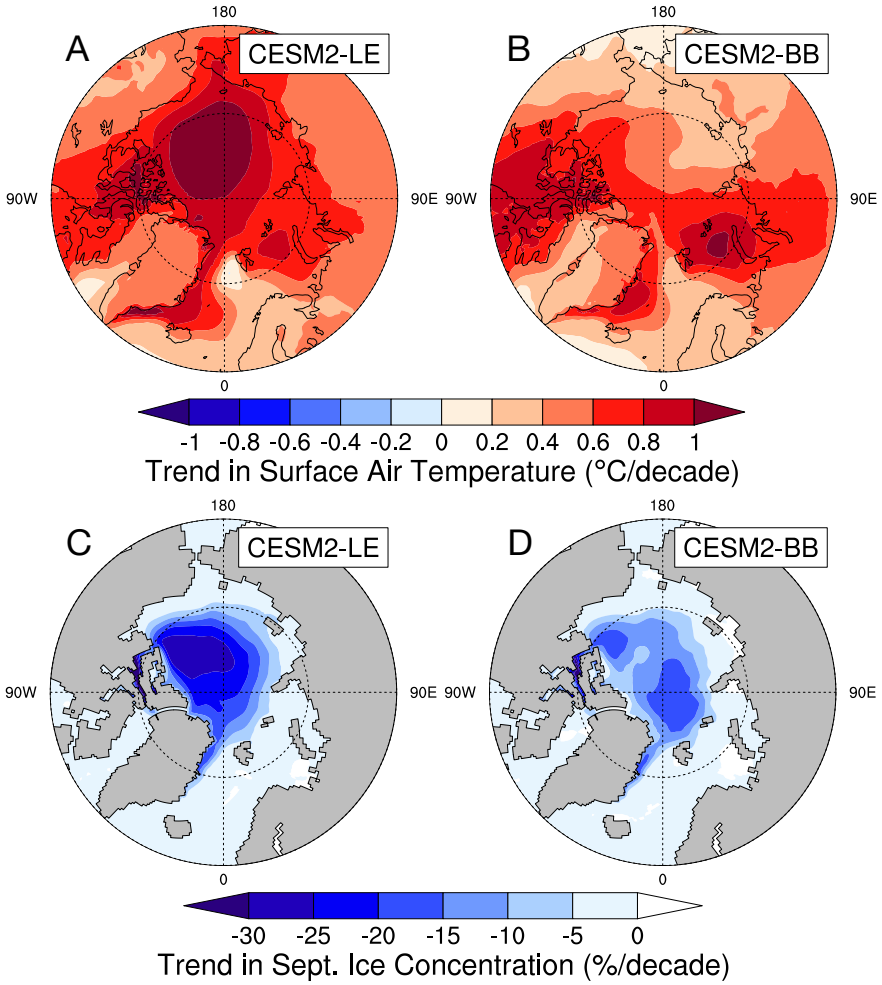

Fig. S3. Spatial patterns of BB impacts. Spatial distribution of the linear trend in (**A and B**) annual surface air temperature and (**C and D**) September sea ice concentration over the GFED period (1997–2014) in (A and C) the CESM2-LE and (B and D) the CESM2-BB.

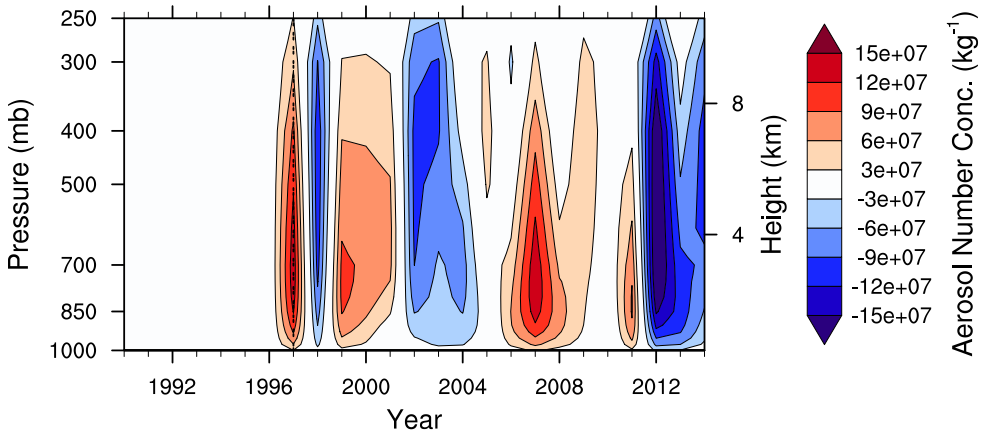

Fig. S4. BB emissions impact on Arctic primary carbon aerosols. Difference (CESM2-BB – CESM2-LE) in Arctic (70–90°N) summer (JJA) number concentration of aerosols in the primary carbon mode with height. Positive differences (red) indicate larger values in the CESM2-BB and negative differences (blue) indicate larger values in the CESM2-LE. The vertical double-dashed line indicates the start of the GFED period.

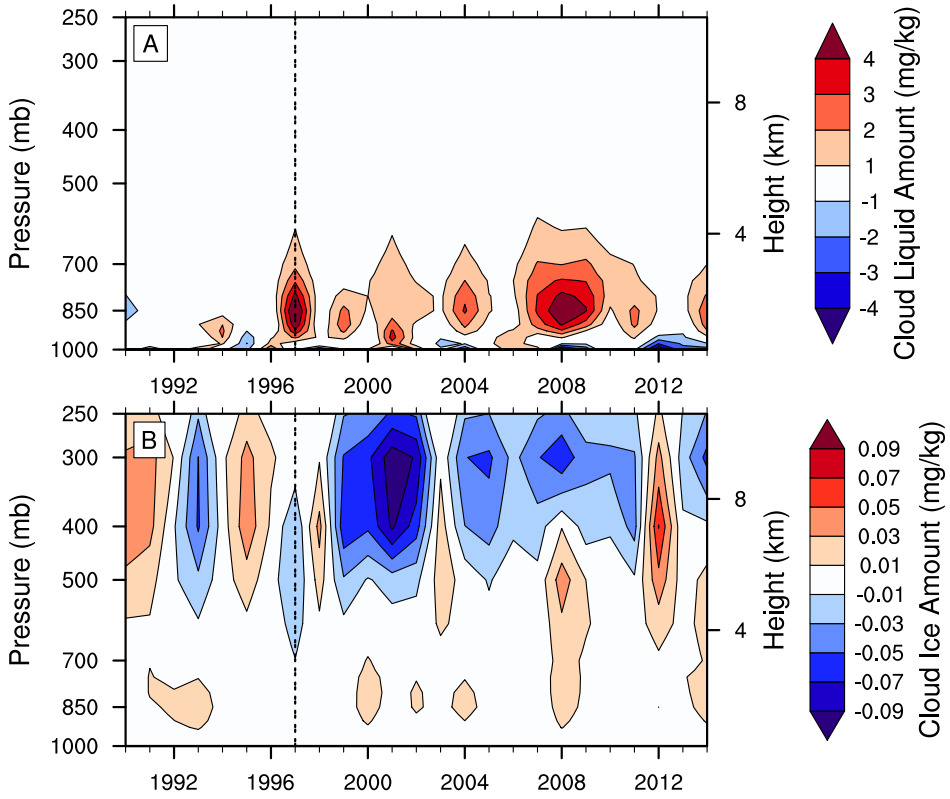

Fig. S5. BB emissions impact on Arctic liquid and ice clouds. Difference (CESM2-BB – CESM2-LE) in Arctic (70–90°N) summer (JJA) cloud (**A**) liquid and (**B**) ice amount with height. Positive differences (red) indicate larger values in the CESM2-BB and negative differences (blue) indicate larger values in the CESM2-LE. The vertical double-dashed line indicates the start of the GFED period. Note the same units but different range of the colorbar for each panel.

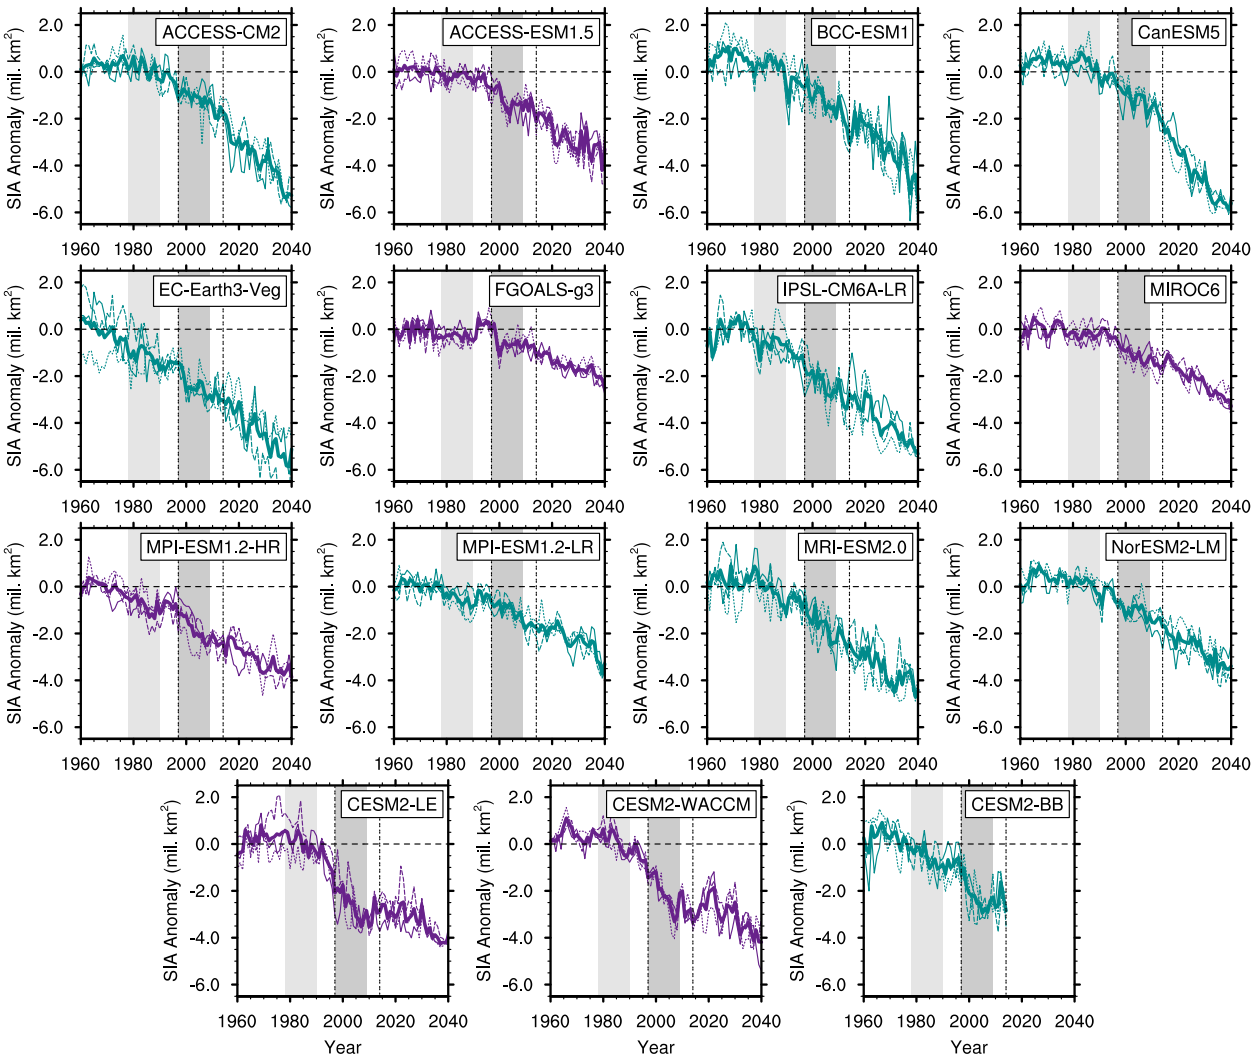

Fig. S6. September sea ice evolution in CMIP6 models. September sea ice area (SIA) anomalies relative to the 1940–1969 average for each CMIP6 model. Models in the sensitive category are shown in purple and the ones in the not sensitive category are shown in turquoise. For each model, the first three ensemble members are shown as thin lines and the ensemble mean is shown by the thick line. The light gray shaded region corresponds to the reference period 1978–1990 and the dark grey shaded region corresponds to the acceleration period 1997–2009 (see Materials and Methods for more details). The horizontal dashed line indicates no anomalies and the two vertical double-dashed lines indicate the GFED period. The last row shows the CESM2-LE, the CESM2-WACCM and the CESM2-BB for comparison, only using the first three ensemble members.

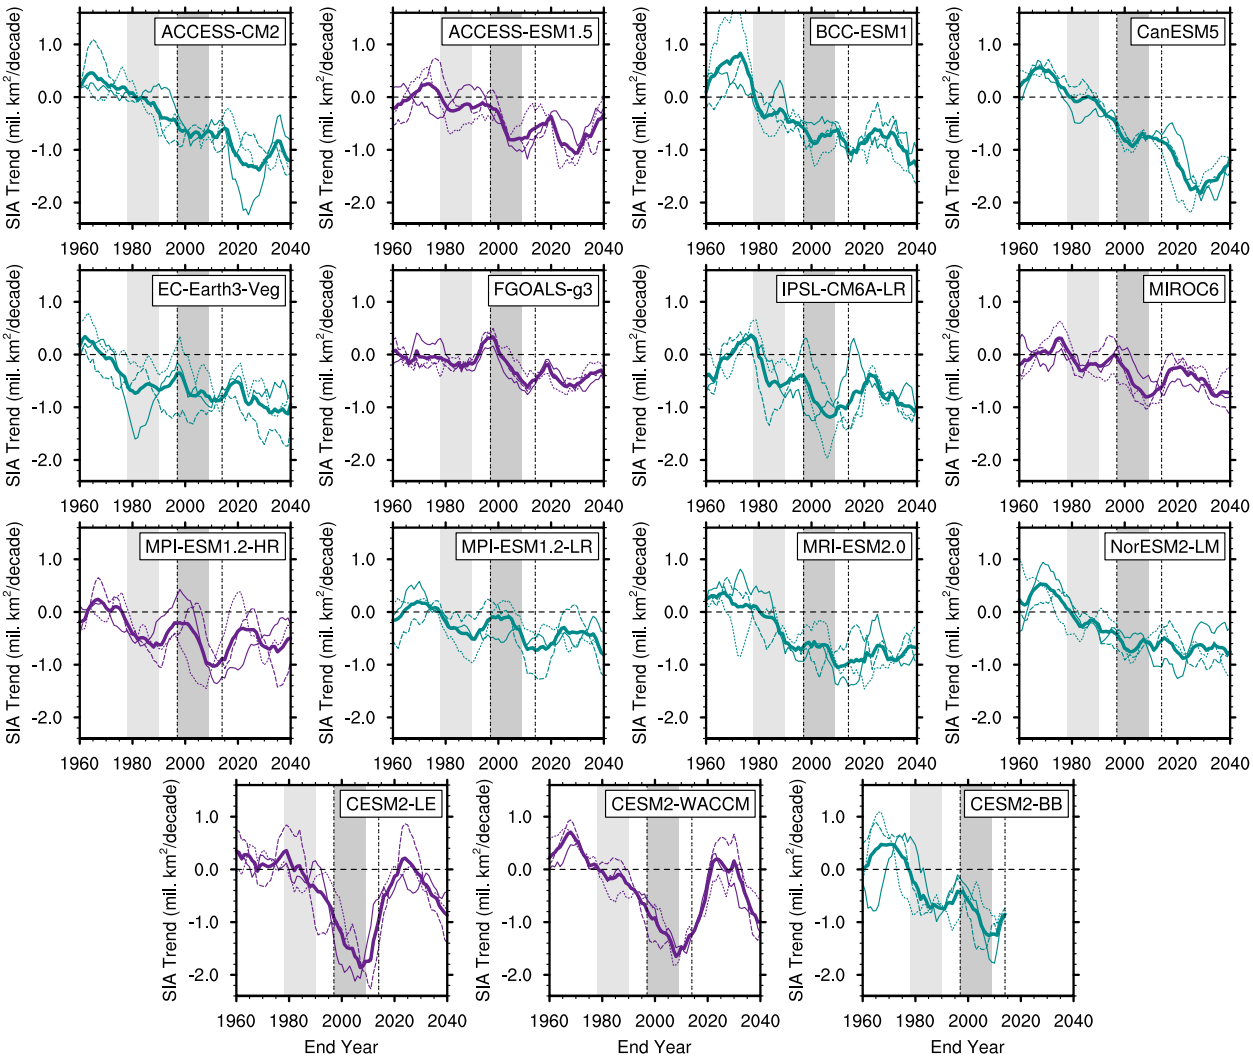

Fig. S7. September sea ice area trends in CMIP6 models. As in Fig. S6, but for 20-year linear trends in September sea ice area (SIA). The horizontal dashed line indicates no trend. Values on the x-axis indicate the end year of the 20-year period over which the linear trend is computed.
